The authors state the results of what they call the Sarcina test (using *Micrococcus lysodeikticus*, supplied by the Mead Johnson laboratories). The conditions of the test are described. The normal tears provoked total lysis even in dilutions of 1 to 2,000, with 24 hours contact at 37 degrees. Greater dilutions produced partial action, there being traces of lysis even in dilutions of 1 to one million. For shorter periods of incubation, greater concentrations were required. The lysozyme content in pathologic secretions varied with the period of evolution of the disease, the proportion being increased in the earlier days of the disease for any type of ocular inflammation. The highest titer of lysozyme was experienced in those ocular affections in which bacteriologic examination was negative. (4 figures, 7 tables, 3 graphs, bibliography.)

TUMORS

Love, J. G., and Benedict, W. L. Intraorbital tumors. Jour. Amer. Med. Assoc., 1945, v. 129, Nov. 17, p. 777.

Since the transcranial approach to tumors of the posterior orbit gives maximal exposure and direct visualization of the structures involved, and since at the same time it permits removal of an intracranial extension of the tumor, the authors feel that this is the procedure of choice. A neurosurgeon should be chosen for the surgical treatment of such retrobulbar orbital tumors. The diagnosis and treatment of posterior orbital tumors in patients aged two months to 53 years are described. Symptoms were varied, although proptosis was by far

the most common. Meningioma was the most common tumor. Thirteen tumors had extended beyond the orbit. All patients recovered but one, an infant who died of hyperthermia.

Morris Kaplan.

Offret, G. Primary epithelial tumors of the ciliary region. Arch. d'Opht., 1945, v. 5, No. 2, p. 11.

In an extensive monograph, Offret reviews the subject of epithelial tumors of the ciliary body. He describes simple primary epithelioma as the least frequent neoplasm of the ciliary body. It develops in eyes which have suffered from traumatism or infection, particularly in elderly individuals, and is characterized by its large size, by pigmentation, degenerative changes, slow growth, association with cysts of the iris and ciliary body, and usually by the absence of metastases.

A second, more frequent primary malignant tumor, often called diktyoma and found in children from two to eight years of age, is described as "type retine." Nonpigmented, quite flat, and accompanied by increased intraocular pressure, this tumor is often mistaken for a retinoblastoma. Histologically it is made up of interlacing ribbons or membranes of one to many layers of cells, often with glandular tube formation. Rosettes are occasionally seen. There is an inconspicuous connective-tissue stroma. Hemorrhage into the tumor and areas of necrosis are frequent. Extension is limited, although perforation of the globe has occurred. The malignancy is more histologic than clinical.

The benign ciliary epithelial tumors are common; in 1932 Wolff made 58 observations. Characteristically they produce no clinical symptoms, are small in size, and demonstrable only on

microscopic examination of enucleated eyes. With few exceptions they are encountered only in individuals over 50 years of age. Histologically, these tumors are destructive because the epithelium has no connective-tissue supporting structure and no distinct vascular supply. Offret strongly opposes Fuchs's classification of these benign epithelial tumors as inflammatory and senile epithelial excrescences of the ciliary body.

Phillips Thygeson.

Paufique, L., and Chavanne, H. Glioma of the chiasm. *Jour. d'Opht.*, 1944, v. 3, No. 3, p. 229.

A new case of glioma of the chiasm is reported. The patient, a man 22 years old, first developed muscular asthenia, loss of appetite, apathy, and loss of weight, in March, 1942, followed by signs of diabetes insipidus. In August, 1943, difficulty in reading developed and rapid loss of vision until there was light perception only. At this time he showed marked loss of weight, hypothermia, and loss of secondary sexual characteristics. There were no motor nor sensory neurologic findings other than the optic-nerve disturbance. X-ray studies of the skull were normal. Operation, performed in October, 1943, revealed a basal arachnoiditis. There was marked increase in the volume of the right optic nerve and chiasm. On puncture, viscous fluid was obtained from the chiasm, comparable to that found in glioma. Post-mortem examination revealed a neoplasm invading the entire region of the third ventricle. The chiasm was cystic, increased in volume. Diagnosis: glioma, histologically confirmed. A discussion of the signs and symptoms of tumors with chiasmal findings is presented.

Phillips Thygeson.

INJURIES

Curtis, G. H. Contact dermatitis of eyelids caused by antioxidant in rubber fillers of eyelash curlers. *Arch. Dermat. and Syph.*, 1945, v. 52, Oct., p. 262.

Seven cases of contact dermatitis due to sensitivity to the rubber filler of eyelash curlers were observed. In five cases the allergen was found to be phenyl-beta-naphthylamine, an antioxidant used in the manufacture of rubber fillers. In addition to the history of contact and positive reactions to patch tests, the dermatitis may be distinguished from other common dermatoses of the eyelids as well as from eczematous contact dermatitis due to other allergens by the facts that (1) the dermatitis is subacute rather than acute and vesicular; (2) it tends to occur in linear bands; (3) if it involves the whole of the upper lid there is a narrow band of normal skin along the tarsal fold and between the dermatitis and the margin of the lid, and (4) the eyelashes show artificial curling.

Theodore M. Shapira.

Obal, A. Comparison of the healing of perforating eye injuries before and after the introduction of milk injections (computation of the years 1907-1908 and 1937-1940). *Klin. M. f. Augenh.*, 142, v. 108, Sept.-Oct., p. 614.

In the years 1907 to 1909, 190 patients had been treated in the University Eye Hospital in Vienna for perforating eye injuries. One half of the eyes with lens injuries and 15.8 percent of those without lens injuries were lost. In the years 1937 to 1940—that is, after the introduction of parenteral milk injection—201 patients were treated. Only 31.8 percent of the eyes

with lens injury and 9.1 percent of those without lens injury were lost. One must remember, however, that in the latter period patients with intraocular infection were given not only milk injections, but also typhoid vaccine and sulfa drugs. (References.)

SYSTEMIC DISEASES AND PARASITES

Mendonça de Barros, J. **Treatment of ocular syphilis.** *Arquivos Brasileiros de Oft.*, 1945, v. 8, nos. 4 and 5, pp. 110-125; also *Rev. Brasileira de Oft.*, 1945, v. 4, Dec., pp. 91-110.

This is a 16-page review of the whole subject, with emphasis upon the principle that the syphilitic patient should have thorough treatment for his general condition, and not merely for the ocular manifestations. W. H. Crisp.

Pacheco Luna, R. **Guatemalan onchocercosis.** *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Jan.-Feb., pp. 13-17.

An academic discussion of the disease is presented, including history, parasitology, and general symptoms. There are characteristic ocular symptoms which are grave, and may be followed by blindness. Photophobia, blepharospasm, and foreign-body sensation are due to a chronic keratitis, plastic uveitis, and filariae in the vitreous. The condition may terminate in phthisis bulbi and hypotension. Actual intraocular tumefaction also occurs; sometimes the tumors can be extirpated, but the disease progresses unfavorably. Treatment is unsatisfactory.

Edward Saskin.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Graff, Th. **War restrictions in ophthalmologic optics.** *Klin. M. f. Augenh.*, 1942, v. 108, Nov.-Dec., p. 745.

Graff discusses the restrictions and regulations necessitated by the war. The manufacturing of biconcave and biconvex spheric and cylindric lenses as well as plano-convex, plano-concave, and periscopic lenses is forbidden. Only two types of bifocal lenses are allowed. The difference between distance and near parts must not be smaller than one diopter. When the total refractive error is greater than five diopters, lenses may be prescribed only in differences of one-half diopter; when it is greater than 10 diopters, difference must be one diopter. In cylindric lenses one-half-diopter differences are allowed. Tinted, ground lenses may be manufactured only to allow 50-percent or 75-percent absorption in the visible spectrum and total absorption of the ultraviolet rays. Clampover glasses are not permitted. Gradually ophthalmologic instruments will be strictly standardized. The author hopes that such restrictions will be perpetuated in the postwar period.

F. Nelson.

Howe, P. J., and Osterman, M. R. **Medical social service with glaucoma patients.** *Sight-Saving Rev.*, 1945, v. 15, Summer, p. 80.

The social worker must give glaucoma patients more than financial relief. Such patients particularly need the relief from anxiety and fear which come from a free discussion with his social worker, as well as help in carrying out his part of the treatment. This

service is needed as much by private patients as by clinic patients.

R. Grunfeld.

Koch, F. L. P., and Smith, V. M. *Glaucoma clinic procedures*. *Sight-Saving Rev.*, 1945, v. 15, Summer, p. 92.

The procedure in use at the demonstration glaucoma clinic is described in detail.

R. Grunfeld.

Law, F. W. *Some public health aspects of ophthalmology*. *Sight-Saving Rev.*, 1945, v. 15, Spring, p. 13.

In this address the author ranges over the whole field of ophthalmology. In the early history of ophthalmology in England most of the practitioners were unqualified though they achieved places of eminence in the courts. The tremendous strides made in industrial ophthalmology are discussed. Improvements in industrial and domestic lighting are described. The problem of the relation of the ophthalmologist to the optometrist and its projected solution in England are discussed. Since there are not enough ophthalmologists to accomplish all the work of refraction it is suggested that the hospitals employ properly trained, medically supervised opticians. After describing and praising orthoptic exercises the author denounces as pure charlatanism the practice of eye exercises to improve vision or to cure cataracts.

Morris Kaplan.

Minton, Joseph. *The one-eyed worker*. *Brit. Jour. Ophth.*, 1945, v. 29, Sept., pp. 472-476.

Investigations of the employment of one-eyed workers in industry, made in 1938, are reported.

Persons who have lost an eye in

childhood are in no way handicapped and have full confidence in the carrying out of their work. One finds men of this group employed in the building trades, in the engineering trades, and in the tool-making industry. They suffer few disadvantages in the labor market.

An investigation of 100 men and women who had lost an eye in adult life showed that the greatest number of injuries occurred in the mining, metal, and engineering industries, in such processes as hammering, chipping, boring, or milling.

After the excision of an eye, the patient must adjust to new visual conditions. The length of time required varies from a few weeks to several months. Women are slow to adjust, and their depth perception may long remain inaccurate. The loss of the dominant eye produces greater disability and delays adjustment to monocular vision. An instrument for determining whether the one-eyed person is left with the dominant eye is described.

The period of enforced absence from work should not exceed two or three months, but many men do not return to work for six to nine months.

Detailed accident statistics kept by safety departments indicate that there is no evidence to show that one-eyed persons are more prone to accidents than the normal-sighted.

Occupations considered suitable for one-eyed people are listed by the author. If the vision of the remaining eye is 6/6 or 6/9, the one-eyed patient can follow comfortably all occupations involving close work, except operations in the metal and engineering trades, which may cause injury to the remaining eye. If the vision is 6/12, constant close work is not recommended, but employment in the food

and distributive trades or in the building trades is advised. One-eyed drivers with 6/12 vision are considered safe. If the vision is less than 6/12, gardening, farming, and domestic service are the most suitable occupations.

The danger of injury to the remaining eye should always be considered when men wish to return to work in the engineering and metal trades. Miners should not be reemployed in underground work. Most one-eyed men and women are fit for most jobs, but the safety of the remaining eye must be the first consideration.

Edna M. Reynolds.

Minton, Joseph. Vision and the selection of personnel in industry. *Sight-Saving Rev.*, 1945, v. 15, Summer, p. 67.

All occupations may be classified in five groups on the basis of visual requirements. The occupations in group 1—the manufacture of silk yarns, silk hose, electric-light bulbs, and watches, for example—require very good eyesight (6/6 in one eye, 6/36 in the other eye). Those in group 2—all clerical work, engineering, and the driving of vehicles—need good eyesight (6/12 and 6/36). All industrial occupations except those in which depth perception is necessary form group 3. Only fair vision is needed (6/12 and 6/36 or one blind eye). Workers in group 4, those in outdoor occupations such as building trades, carpentry, dock labor, and portering may have weak eyesight (6/24 and 6/36). Group 5 contains a great number of industrial and other occupations which are suitable for the blind and the partially blind. A list of these occupations has been prepared by the National Society for the Prevention of Blindness. R. Grunfeld.

Polack, M. Tscherning and his work. *Ann. d'Ocul.*, 1940, v. 177, no. 5, pp. 179-187.

Marius Hans Erik Tscherning was born in 1854, in Denmark, where he spent most of his life. His 75 contributions to ophthalmology, including his exemplary textbook on physiologic optics, are a lasting monument to a truly great man. He was admitted to the degree of Doctor of Medicine in 1887, in Paris, and remained there until 1910, when he became professor of ophthalmology in the University of Copenhagen. He retired from teaching in 1925, but continued his investigations until his death in 1939. Chas. A. Bahn.

Sorsby, Arnold. The incidence and causes of blindness in the British Commonwealth. *Brit. Med. Jour.*, 1945, Oct., 27, p. 557.

The number of blind persons in the British Isles is between 90,000 and 100,000. In the Dominions, between 40,000 and 50,000 white persons and about 10 millions natives are blind. There has been a marked decline in the incidence of blindness in childhood and early youth and an increase in later life. Further decline in the incidence of blindness in youth will soon come to an end. Even now about 65 percent of blindness in youth is caused by congenital factors. Reduction in the incidence of blindness in the future can be achieved only by intensive research in the problems of congenital diseases, maternally transmitted infections, cataract, glaucoma, and the diseases of the aged. In the native population of the British possessions, the incidence of blindness could be reduced immediately and effectively by an intensified and organized effort to treat

the widely prevalent ocular infection with sulfa drugs and penicillin.

R. Grunfeld.

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Stone, L. S. Heteroplastic lens grafts related to factors inhibiting lens regeneration in *Triturus*. Proc. Soc. Exper. Biol. and Med., 1945, v. 60, Oct., p. 10.

The presumptive lens-forming ectoderm over the optic vesicle of embryos in the early tail-bud stage was exchanged between *Amblystoma punctatum* and *Triturus torosus*. Normal lenses developed. Some of them were observed for 98 days. When the lenses of the two species were exchanged between larvae about 17 mm. in length, the exchanged lenses survived and grew well for a long time. If the heteroplastic lenses were excised 70 days after the exchange, regeneration of the lens tissue took place in the *triturus*

eye from the dorsal rim of the iris, as it normally occurs following lensectomy. In the *amblystoma* eye, however, no such regeneration of the iris tissue takes place since under normal condition no regeneration of the iris tissue occurs after lensectomy.

Lenses of young adult *amblystoma* eyes were implanted in lensectomized eyes of adult *Triturus viridescence*. If the lenses survived they became endowed with the capacity to inhibit new formation of lens from the dorsal rim of the iris, but if the lens became cataractous the inhibitory effect diminished.

If lenses from the tadpole eye were implanted, or if wax spheres of the same size as normal lenses were placed in lensectomized eyes of the *triturus*, no inhibitory effect was exercised, and a new lens developed from the dorsal rim of the iris, proving that mechanical factors are not responsible for the inhibition.

R. Grunfeld.

PAN-AMERICAN NOTES

Edited by DR. M. URIBE TRONCOSO
500 West End Avenue, New York 24

Communications should reach the editor by the twelfth of the month.

THE SECOND PAN-AMERICAN OPHTHALMOLOGICAL CONGRESS

This Congress was held at Montevideo, Uruguay, from November 26 to December 1, 1945. It was a decided success from the standpoint of attendance. Although the United States ophthalmologists were few in number, owing to the great difficulties in transportation, some representative members were present. Among them we must mention Captain Clifford A. Swanson, representing the Navy; Commander Walter P. Griffy, representing the Public Health Service; Dr. Ramón Castroviejo, representing the American Ophthalmological Society; Dr. Conrad Berens, representing the American College of Surgeons; Dr. Thomas D. Allen of Chicago, and Dr. Joseph I. Pascal of New York. Latin-American countries were, on the other hand, very well represented. Brazil had the largest number, with 123 members present; Chile had 16; Cuba, 19; Mexico, 3; Bolivia, 3; Ecuador, 1; Guatemala, 1; Colombia, 2; Costa Rica, 2; Paraguay, 5; Peru, 7; Dominican Republic, 1; Venezuela, 3. Uruguay, where the Congress was held, had a representation of 70 members. The Argentinian ophthalmologists did not attend the Congress officially. Even members of the Board of Directors of the Congress withdrew, because of the political conditions through which Argentina is passing. The Asociación Médica Argentina decided earlier in November, 1945, to stop all scientific activities of its members as a civil protest against the state of constitutional abnormality, which, unfortunately, has existed in that country for some time. The Argentine Ophthalmological Society,

which is a part of the Medical Association, decided to find out by a plebiscite if its 80 members could attend the Congress at Montevideo as an exception to the general rule. The plebiscite had 70 members in favor of cessation of all scientific activities against 5 in opposition. The Society then addressed an official communication to the Board of Directors of the Congress, informing them of the withdrawal of Argentine members.

Dr. Vazquez Barriere, president of the Board, opened the meeting by stressing the necessity of inter-American coöperation for the advancement of ophthalmology and the prevention of blindness. Dr. Harry S. Gradle, president of the Congress, could not attend the meeting because of illness. His address was read by Professor Alvaro of Brazil, and his recommendation to form a Board of Ophthalmology for Latin-America was later acted upon and accepted.

The meetings were held according to the program previously published in this column and were quite successful and well attended, although the meeting place was a hotel somewhat distant from the city of Montevideo. The inaugural session was attended by the municipal and university authorities and members of the Diplomatic Corps. Dr. Arruga arrived from Spain after a difficult and delayed trip. His discussion of the treatment of detachment of the retina was a valuable contribution to our knowledge of the subject.

The Congress decided to change its name to "Pan-American Association of Ophthalmology." The following officers of the new association were elected at the

Montevideo meeting: president, Dr. Harry S. Gradle; honorary president, Professor Alberto Vazquez Barriere; vice-presidents: Dr. Francisco Belgeri (Argentina), Dr. Frank Brawley (U. S. A.), Dr. J. Pereira Gomes (Brazil), Dr. Frederick C. Cordes (U.S.A.), Dr. J. A. MacMillan (Canada), Dr. Alex Aguero (Costa Rica); Dr. G. Espildora Luque (Chile), Dr. R. Pacheco Luna (Guatemala), Dr. A. Torres Estrada (Mexico); executive secretaries: Professor Moacyr E. Alvaro (Brazil) and Dr. Conrad Berens (New York).

The Committee on Ophthalmological Education appointed a president, Dr. Jorge Valdeavellano (Lima, Peru), and three secretaries whose work will be divided as follows: Dr. Thomas D. Allen in charge of Canada and the United States; Dr. Miguel Branly (Cuba) in charge of Mexico, the continental countries of Central America, the islands of the Caribbean, Venezuela, and Colombia; and Dr. Paul Rodriguez Barrios (Montevideo, Uruguay) in charge of Ecuador, Peru, Bolivia, Chile, Argentina, Paraguay, Uruguay, and Brazil.

The Committee on Kellogg Fellowships appointed Dr. Harry S. Gradle, Dr. Conrad Berens, Dr. Tomas Yañes, and Prof. Moacyr E. Alvaro to represent the Association.

A committee was appointed to draw up a constitution and by-laws for the new Association. This consists of Dr. Tomas Yañes, Dr. Conrad Berens, and Professor Alberto Vazquez Barriere.

The next meeting of the Pan-American Association of Ophthalmology is planned for February, 1948, in Havana, Cuba. All ophthalmologists in the Western Hemisphere will be invited to become members of the Association. Membership entitles receiving the official publication "Ophthalmologia Ibero Americana," which has been in existence for several years and is printed in three languages: English, Spanish, and Portuguese.

Communications concerning the Association should be addressed to Prof. Moacyr E. Alvaro (1151 Rua Consolação, São Paulo, Brazil) if mailed south of Panama, and to Dr. Conrad Berens (301 East 14th Street, New York 3, N.Y.) if mailed north of Panama.

NEWS ITEMS

Edited by DR. DONALD J. LYLE

904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month.

DEATHS

Dr. Wylie M. Ayres, Cincinnati, Ohio, died December 22, 1945, aged 71 years.

Dr. Frederick Brown, Valley City, North Dakota, died November 13, 1945, aged 65 years.

Dr. William C. Comee, Green Bay, Wisconsin, died December 8, 1945, aged 59 years.

Dr. John F. Curtin, Minneapolis, Minnesota, died December 25, 1945, aged 56 years.

Dr. Clarence P. Franklin, Philadelphia, Pennsylvania, died December 11, 1945, aged 75 years.

Dr. Lee M. Goodman, Jersey Shore, Pennsylvania, died recently, aged 64 years.

Dr. Edgar S. Harris, Independence, Missouri, died November 27, 1945, aged 68 years.

Dr. Isaiah W. Haughey, Fort Collins, Colorado, died December 5, 1945, aged 77 years.

Dr. Max L. Holland, Roanoke, Virginia, died November 9, 1945, aged 37 years.

Dr. Howard E. Jones, Circleville, Ohio, died December 12, 1945, aged 92 years.

Dr. Charles F. Jump, Helena, Montana, died October 23, 1945, aged 63 years.

Dr. William G. Kennon, Nashville, Tennessee, died January 3, 1946, aged 62 years.

Dr. John F. Klinedinst, York, Pennsylvania, died December 6, 1945, aged 78 years.

Dr. Emory L. Kniskern, Muskegon, Michigan, died January 26, 1946, aged 77 years.

Dr. Charles E. Lauder, Viroqua, Wisconsin, died December 6, 1945, aged 79 years.

Dr. David L. Martin, Boston, Massachusetts, died December 6, 1945, aged 71 years.

Dr. John H. F. O'Neil, Chicago, Illinois, died December 20, 1945, aged 61 years.

Dr. William H. Phillips, Cleveland, Ohio, died December 19, 1945, aged 74 years.

Dr. Frank D. Smith, Rochester, Minnesota, died December 8, 1945, aged 64 years.

Dr. Henry M. Smith, Brooklyn, New York, died February 23, 1946, aged 75 years.

Dr. Lee W. Smith, Butte, Montana, died November 18, 1945, aged 53 years.

Dr. Thomas M. Stewart, Cincinnati, Ohio, died December 10, 1945, aged 79 years.

Dr. William G. Stinchcomb, Bellefontaine, Ohio, died December 19, 1945.

Dr. John P. Young, Chester, South Carolina, died November 29, 1945, aged 75 years.

MISCELLANEOUS

FIRST PAN-AMERICAN CONGRESS OF OTOLARYNGOLOGY AND BRONCHO-ESOPHAGOGY. Immediately following and overlapping with the

annual meeting of the Academy in October of this year, the First Pan-American Congress of Oto-Rhino-Laryngology and Broncho-Esophagology will take place, under the sponsorship of the Academy. This Congress will open with a banquet and evening session on Thursday night, October 17th, and will continue on the two subsequent days. The first scientific session will be a joint session with the Otolaryngology Section of the Academy, and three additional sessions will take place on Friday afternoon, Saturday morning, and Saturday afternoon. All interested members of the Academy are strongly urged to plan to remain for the Pan-American Congress, for which an excellent program is being arranged.

The registration fee will be \$5.00.

Executive committee, Pan-American Congress: Gordon B. New, M.D., president; Chevalier L. Jackson, M.D., secretary; Paul H. Holinger, M.D., treasurer.

The Oregon Academy of Ophthalmology and Otolaryngology held its seventh annual Spring postgraduate convention in ophthalmology and otolaryngology from April 15th to April 20th. The guest speakers were Dr. Gabriel Tucker of the University of Pennsylvania Graduate School and Dr. Peter Kronfeld of the Illinois Eye and Ear Infirmary, University of Illinois. Dr. Kenneth C. Swan of the University of Oregon Medical School gave a course on ocular histopathology. Included in the program were lectures on endaural surgery, clinical demonstrations of problem eye cases, intranasal operations, the measurement of astigmatism, brain abscesses, Lempert operation, and cadaver demonstrations.

The International College of Surgeons, United States Chapter, will hold its eleventh annual assembly and convocation in Detroit, Monday, Tuesday, Wednesday, October 21-22-23, 1946.

Surgical clinics in Detroit hospitals will feature the first morning of the Assembly. Thereafter all the meetings, the convocation, and the exhibition will be held in the Masonic Temple, a splendid building affording every convenience.

Copy of the program and detailed information may be obtained by writing Dr. Louis J. Garipey at 16401 Grand River Avenue, Detroit.

SOCIETIES

The fifteenth scientific meeting of the Association for Research in Ophthalmology will

be held in San Francisco, at the Hotel Mark Hopkins on Tuesday, July 2, 1946.

The fifty-second meeting of the Reading Eye, Ear, Nose and Throat Society was held on February 20, 1946, as a joint meeting with the Diplomates' Association of Berks County Physicians. The speaker of the evening was Dr. Harry Rogers, president, American College of Allergy. His talk was a review of the allergies as they apply to the specialties.

At the meeting of the Milwaukee Otolaryngic Society, held on March 26th, Dr. Samuel M. Feinberg, Northwestern University, Cook County Hospital, presented a paper on "Allergy of the eye, ear, nose, and throat: Practical evaluation and management of cases." The discussion was opened by Dr. Theodore L. Squier with Dr. F. Herbert Haessler giving the eye physician's viewpoints and Dr. Frank G. Treskow giving those of the ear, nose, and throat physician.

The Brooklyn Ophthalmological Society held its ninety-sixth regular meeting on April 18th. The scientific program consisted of the following presentations: "Ocular manifestations of skin diseases" by Dr. Nathan Sobel; and "Surgical management of squint" by Dr. Harold W. Brown.

At the annual meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology on April 24th-25th, the following program was presented: "Some interesting phases of war ophthalmology," by Dr. James N. Greear, Jr.; "Pan-American otolaryngology," by Dr. Chevalier L. Jackson; "Anesthesia in ophthal-

mology," by Dr. Walter S. Atkinson; "Retinal arteriolar sclerosis," by Dr. Walter I. Lillie; "Contemporary medical problems," by Dr. Robin C. Buerki; and "Symposium on the hard of hearing," by Captain Fred Harbert.

PERSONALS

Dr. George M. Haik, New Orleans, has been appointed professor of ophthalmology at the Louisiana State University Medical School, New Orleans, succeeding the late Dr. Theodore J. Dimitry.

Major Frederic T. Becker (MC) of Memphis, spoke on "Cutaneous eruptions frequently seen in eye, ear, nose, and throat practice," at the 1946 session of the Medical Association of the State of Alabama.

Dr. Wiley R. Buffington spoke on "Detached retina" at the seventieth session of the Arkansas Medical Society, April 15th-17th.

Dr. Alan C. Woods presented a paper, entitled "Early treatment of eye injuries," before the Medical and Chirurgical Faculty of Maryland at its meeting on April 23d-24th at the Belvidere Hotel, Baltimore.

Dr. James W. White of New York was among the guest speakers at the ninth annual meeting of the New Orleans Graduate Medical Assembly.

Dr. Arthur M. Culler was among the participants in the program given by the faculty members of the Ohio State University College of Medicine on March 27th. He discussed "Progress in ophthalmologic practice and research."

Storz

WALKER OPHTHALMIC COMBINATION UNIT

For Use in Retinal Detachment Operations

WALKER OPHTHALMIC HIGH FREQUENCY UNIT

52

51

This newer model features the use of galvanic current in conjunction with high frequency current. The milliamperage meter is omitted, but a galvanic milliamperage meter is supplied. A double foot switch operates the selection of cathodal galvanic, anodal galvanic, or high frequency current. Either section may be operated independently. It has terminals for attaching the ophthalmoscope and the headlight. Galvanic current supply is from two 2½-volt dry cells, standard size, replaceable from any radio stock. This battery should have a life of from ten to twelve months.

Weight 25 pounds. The carrying case 14½" x 12½" x 10". Receptacle in the bottom for foot switch, line cord, etc. For 110 volt, 50 or 60 cycle A. C.

Accessories for No. 52:

- a. Diapad Electrode
- b. Dual Foot Switch
- c. Walker Handle
- d. Walker Needle
- e. Line Cord

\$247⁵⁰

Has the required micro-current, 25 to 50 milliamperes. Adjustments to a precision of 5 milliamperes in continuous sequence. Double-scale meter, accurate recordings from 25 to 200 milliamperes on the low scale and up to 1000 milliamperes on the high scale. A spring activated control holds the meter control on the high scale at all times, except in actual pre-setting for retinal technique, to obviate damage to the meter. For retinal technique and for other minor surgery procedures by coagulation.

With portable case 10½" x 14½" x 8". For 110 volt 50 or 60 cycle A. C.

Accessories for No. 51:

- a. Diapad Electrode
- b. Foot Switch
- c. Walker Handle
- d. Walker Needle
- e. Treatment Cord
- f. Line Cord

Chungking, China

INTRODUCTION

Difficulties in differentiating trachomatous from nontrachomatous conditions, especially in so-called "borderline" cases, are encountered by every ophthalmologist. In fact, the striking similarity between certain forms of chronic conjunctivitis and trachoma I (McCallan) may make a strict differentiation between the two almost impossible, even to the most experienced. Too often ophthalmologists have to be content with a temporary diagnosis of suspected trachoma, settling upon the exact nature only after subsequent observations.

Although certain clinical peculiarities of trachoma—such as, the peculiar haziness of the lower cul-de-sac as a result of the diffuse subconjunctival infiltration; the typical localization of the papillary hypertrophy and follicular formation, chiefly on the upper tarsal conjunctiva and fornix conjunctivae; the large and irregular sizes of the follicles, which tend to become confluent; the diffuse, hazy appearance over the follicular surfaces as well as over the parts in between; and the presence of Prowazek-Halberstaedter's inclusion bodies or Lindner's initial bodies in the conjunctival smear—may be

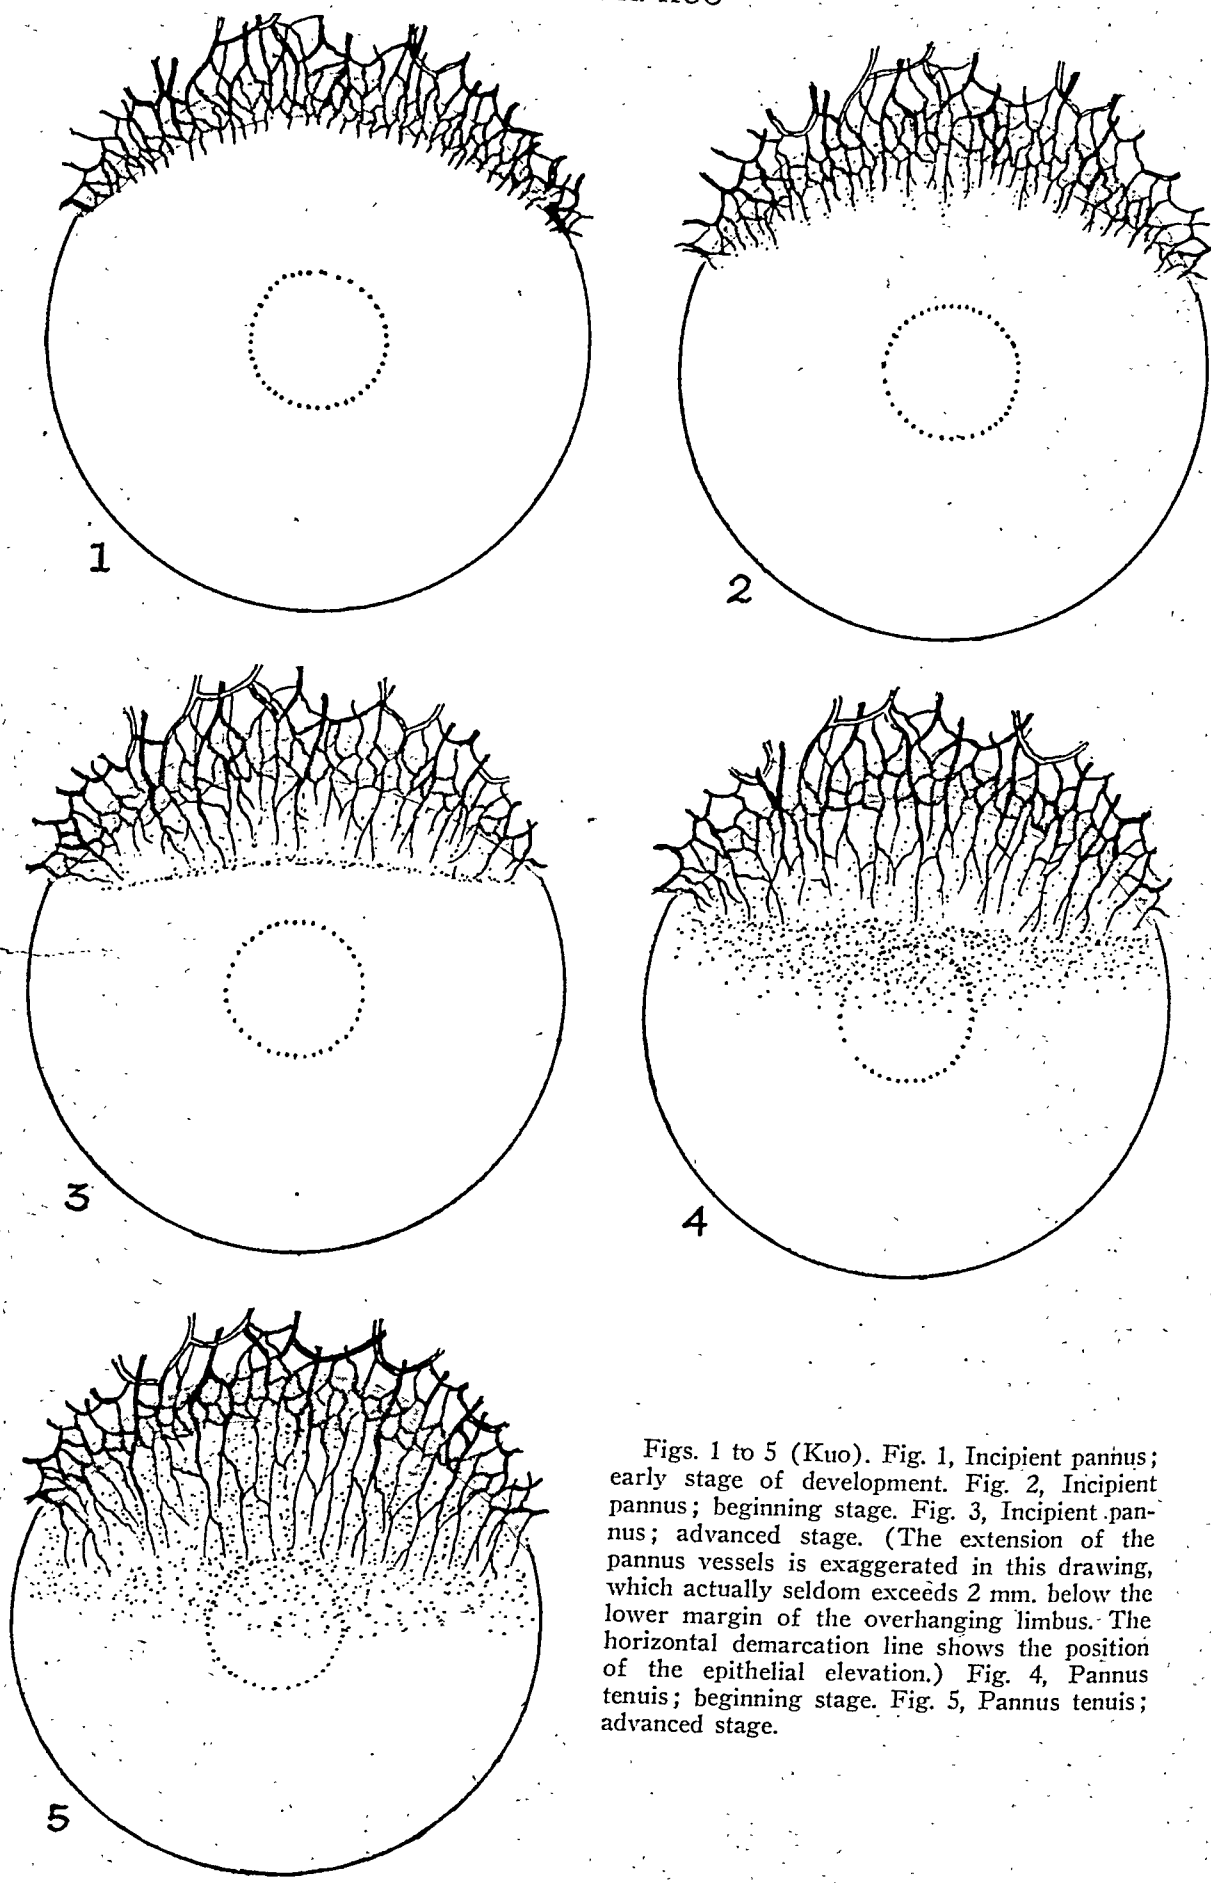

regarded as more or less characteristic of trachoma, cases are not infrequently encountered wherein, if these characteristics are only poorly presented clinically, decisive final diagnosis may become impossible.

When, as in the case of mass physical examination, large crowds are expecting prompt diagnosis, the long search for the inclusion bodies is almost impracticable. Moreover, the inclusion bodies, typical as they are for trachoma, are also demonstrable in the so-called paratrachoma cases of Lindner as well as in cases of "swimming-bath" conjunctivitis, and the failure to find the inclusions cannot be taken as evidence against the positive diagnosis of the disease.

In the course of eight years, I have been searching for some additional characteristics of trachoma in its early stage (trachoma I, McCallan) that will assure a quick and reliable diagnosis of the disease. Because of the lack of slitlamp and corneal microscope, I have had to be content with the aid of a loupe ($\times 20$), but by this means every single case of trachoma is viewed under good focal illumination, and the state of the cornea, particularly of the upper limbal region, is carefully examined.

Following this procedure, I have been able to find that a very high percentage of

(The extension of the pannus vessels is exaggerated in this drawing, which actually seldom exceeds 2 mm. below the lower margin of the overhanging limbus. The horizontal demarcation line shows the position of the epithelial elevation.) Fig. 4, Pannus tenuis; beginning stage. Fig. 5, Pannus tenuis; advanced stage.

cases of incipient trachoma, some even of mild clinical nature, is accompanied by beginning invasion of fine capillaries from the engorged pericorneal vascular plexus into the transparent cornea immediately under the upper limbus. The percentage of this finding is, in fact, so high that one seems justified in designating this sign as pathognomonic for all cases of beginning trachoma. It would be even more apparent if the cases could all be examined under the corneal microscope with the aid of a slitlamp.

INCIPIENT PANNUS

This initial corneal neovascularization, or incipient pannus, as it is to be called, is characterized at its very beginning stage by the presence of fine, short capillary sproutings from the apices of the pericorneal vascular loops (fig. 1) into the transparent cornea, presumably under the epithelium, but above Bowman's membrane.

The looping plexus, which appears somewhat engorged, is clearly visible on the white, opaque background of the overhanging (exaggerated) crescent of the upper limbus. The capillary sproutings, however, are visible only under good oblique focal illumination, without glare, and careful search with the loupe. During this examination the patient has to look downward so as to expose the upper limbus directly to the field of examination.

The white, overhanging limbus, which is invariably present in all Chinese patients, with its crescent form and characteristic network of more or less engorged blood vessels, should not be mistaken for the pannus itself.

This blood-vessel network or vascular plexus presents the picture shown diagrammatically in figure 1, with the slender, lighter arterial branches going over to the grosser, darker venous twigs through many looping formations. The latter part

seems to lie more superficially in front of the former.

The picture is essentially the same as that produced by Leber¹ for "das Randschlingennetz im Limbus." Capillary sproutings are seen shooting from the apices of the vascular loops into the transparent part of the cornea, forming a row of fine, short blood vessels, ending abruptly, almost in a line concentric to the upper limbal margin (fig. 2). These initial capillary sproutings seldom show any side branches forming anastomoses. If they are already filled with blood, they can be seen very clearly under the magnifying loupe ($\times 20$).

Not infrequently, however, they appear in the form of very fine colorless lines, almost indistinguishable from their surrounding medium, probably because they are not yet filled with blood or have already become obliterated during the healing process of trachoma.

Since the overhanging limbus goes only gradually over into the transparent cornea, leaving a rather blurred and indistinct margin, it is sometimes difficult to judge whether the short sproutings are still within the crescent or already in the region of the transparent cornea. The chief criterion for decision is, therefore, the behavior of the apices of the capillary loops. Any "buddings" from these formations must be regarded as being suspicious in nature, even when they may not appear to lie entirely in the transparent corneal region.

It should be noted that, in a large majority of cases, these beginning vascular sproutings are seen, within apparently normal transparent cornea, immediately beneath the opaque overhanging crescent of the upper limbus. It would seem that the vascularization process takes place before any apparent changes in the form of cellular infiltration under the corneal epithelium become evident. The presence

of Herbert's pits is encountered only in exceptionally rare cases.

The later stage of the sproutings is much easier to recognize. Here the capillaries usually reach a distance of 1 to 2 mm. beneath the upper limbus (fig. 3). through proliferation, they become more abundant in number, sending out side branches, so that a semilunar region of the cornea occupied by a delicate capillary network results.

If the pupil is fully dilated under a mydriatic, one can best watch the beautiful picture of this capillary plexus with a direct electric ophthalmoscope (+20) in the darkroom. During this examination, the patient looks downward, and the upper limbal region should be viewed from above. In this way, the vascularized corneal region comes partly under the field of the illuminated pupil, and the blood vessels appear as clear-cut, dark lines on a shining red background.

As the condition progresses, the blood vessels become more engorged and evident, sending out anastomoses to the fellow vessels, forming another series of capillary loops which, in turn, give rise to further capillary sproutings. Here the capillaries also end, quite abruptly; this time in an almost horizontal line.

Although the intercapillary spaces in this semilunar corneal region may remain apparently normal and transparent, that part of the corneal surface immediately central to the abrupt endings of the invading vessels now begins to present some epithelial elevation or unevenness, so that a more or less distinct borderline can be seen, separating the pannus region from the normal, transparent part of the cornea (fig. 3).

Farther ahead of the epithelial elevation, the corneal surface appears to be occupied by less sharply defined, superficial opaque lines going in the direction of the invading vessels or by a finely punctate

haziness (fig. 4) which results from the cellular infiltration under the corneal epithelium. This constitutes the cause of the impaired vision before the pannus vessels have quite reached the pupillary region.

What follows later in the pannus development no longer, in fact, belongs to the stage of incipient pannus. With the farther advance of the arcade of new capillary loops, a somewhat dense vascular plexus is at last formed (fig. 5).

As the process of the subepithelial cellular infiltration advances, the corneal epithelium over the pannus vessels becomes more rough and hazy. Cases have been observed in which finely punctate, grayish-white calcified, subepithelial aggregations are seen scattered on the dendritic branches of the anastomosing vessels, reminding one of snow flakes on a bare tree. Thus, the cornea appears definitely cloudy, uneven, and covered with engorged superficial blood vessels.

Different kinds of pannus trachomatous can be distinguished by the degree of the subsequent fibrous-tissue formation: pannus tenuis, when the blood vessels are scarce and the fibrous tissue thin and recent; pannus vasculosus, when the blood vessels are more densely arranged and engorged; pannus crassus, when greatly engorged blood vessels are seen on top of the thickened fibrous tissue, simulating a fleshy appearance; and pannus sarcomatosus, if this fleshy appearance is so pronounced as to give some degree of tumorlike prominence.

A STATISTICAL SURVEY

In order to ascertain to what extent the beginning stage of trachoma is actually associated with incipient pannus, my co-workers and I have utilized the material obtained from the mass physical examinations of marine volunteers in the Chungking Army Hospital during June, 1945,

to make a statistical survey on this subject. The examinees, a total of 2,370, were all males ranging in age from 20 to 35 years, inclusive.

Each individual was examined carefully for his conjunctival and, particularly, for his corneal condition. The corneal examination was made under loupe magnification and well-concentrated focal illumination. In each case, special attention was given to the upper limbal region.

As classification for the trachoma itself, the system of McCallan was adapted. Among the total of 2,370 persons thus examined, 1,692 individuals, or 71.392 percent, were found to be suffering in various degrees from the disease.

The number of individuals suffering

TABLE 1

NUMBER AND PERCENTAGE OF TYPES OF TRACHOMA DIAGNOSED IN 1692 VOLUNTEERS

Stage of Trachoma (McCallan)	No. Individuals Found	Percentage in Forms of Total Trachoma Incidence

Trachoma II	193	11.40
Trachoma III	35	2.07
Trachoma IV	0	0.00

of mixed infection will be considered presently.)

Still more interesting are the interrelationships between the various trachoma stages and the various degrees of pannus formations as shown in table 2. It is

TABLE 2

STAGES OF TRACHOMA AND OF PANNUS IN 1692 VOLUNTEERS

Stages of Trachoma	Pannus incipiens		Pannus tenuis	
	number	percent	number	percent
Trachoma I (1464 cases)	1315	89.82	0	0
Trachoma II (193 cases)	184	95.34	9	4.66
Trachoma III (35 cases)	24	68.57	9	25.71

from different stages of trachoma and their percentages in terms of the total trachoma incidence are given in table 1.

It is significant that the incidence of trachoma III is low and that that of stage IV is altogether absent. This is probably due to the fact that those who should have reached stage IV have avoided examination, since they were fairly certain not to be accepted for the service. Another factor which may explain this low incidence is that among student bodies where personal habits of cleanliness are often emphasized, the possibility of mixed infection is greatly reduced. (The role

conspicuous that no higher degree of pannus formation than that of the tenuis type is found, in exact agreement with the relatively mild type of trachoma prevalent among the examinees.

The total number of pannus-positive cases associated with each stage of trachoma are shown in table 3. The total number of pannus-positive cases was 1,541 or 91.07 percent of the total (1,692) trachoma cases found.

[The incidence of color blindness is given here only for the sake of completeness. Among the 2,370 persons examined, 83 (3.50 percent) were found to be red-

Trachoma III	35	33	94.27

green blind; 19 (0.8 percent) to be red-green-color feeble. Ishihara charts were used for the examinations throughout.]

The results of the data obtained may be summarized as follows: (1) A rather high percent (71.392) of Chinese young men are infected with trachoma. Since most of the volunteers examined were students from various middle schools and colleges, it can be said that the examinees were of the student class. (2) A majority (86.52 percent) of these cases could be classified in the early stage, or Trachoma I. Only small percentages are found in the second and third stages: trachoma II (11.40 percent); trachoma III (2.07 percent). Trachoma in the fourth stage was altogether absent. (3) Close relationships are observed between the stage of the trachoma and the degree of the pannus formation in a progressive proportion (table 2). The incidence of incipient pannus to trachoma in its very early stage is found to be sufficiently high (89.82 percent) to justify its diagnostic value. This is especially significant when it is considered that, had the slitlamp been used, a full percentage of the incidence might have been anticipated.

DISCUSSION

The significance of incipient pannus for the early diagnosis of the early stage of trachoma can be fully appreciated only when one admits that the corneal affection is specific and primary in nature and

not to be regarded as a secondary infection from the palpebral conjunctiva. This was once a controversial point.

Statements are frequently made that the corneal process is but a result of the constant rubbing of the rough conjunctival surface against the cornea so that the corneal epithelium is mechanically inoculated with the trachoma virus. Accordingly, the development of pannus trachomatous never takes place before the trachomatous process on the lid conjunctiva has reached a certain degree of intensity.

This concept seems further strengthened because of the apparently normal condition of the bulbar conjunctiva during the specific process of inflammation. Since the introduction of the slitlamp examination into the field of clinical ophthalmology, however, this concept has been proved erroneous.

As mentioned by Duke-Elder,² it was Busacca (1933) who studied the biomicroscopic and histologic pictures which occur in the corneal epithelium as initial changes of the trachomatous process. Busacca found that these initial changes usually take the form of an avascular, superficial keratitis; that the picture suggests a primary attack on the corneal epithelium by the virus; that the subsequent vascularization or pannus formation is but a defense reaction of the normally avascular tissue to the invading virus.

In addition to this, the most recent histologic research has proved definitely that the bulbar conjunctiva is involved at the very beginning stage of the disease in the form of subconjunctival cellular infiltration, especially of plasma cells, usually with cellular accumulations in the region of the blood vessels and sometimes with the formation of true follicles.

To use the words of Duke-Elder: "The disease is less fully developed than in the palpebral conjunctiva, but it may attack

the bulbar conjunctiva first, and the evidence points to the fact that it is a primary infection and not a mechanical contact infection from the lid."

In describing the condition of the cornea, it was specifically mentioned "that some degree of pannus is present in every case of trachoma and that in many cases its earliest stages are detectable by the slitlamp contemporaneously with the appearance of the first signs of inflammation in the conjunctiva tarsi. These facts indicate that the corneal infection is specific and primary, not secondary and incidental."

That incipient pannus must appear in every case of early trachoma is, therefore, not a matter of speculation, but a matter of theoretical possibility. The relatively low incidence of 89.82 percent in the present series is to be ascribed entirely to the use of a loupe, the magnifying power of which is, naturally, not to be compared with that of a corneal microscope, aided by an ideal focal illumination of the kind afforded by the slitlamp.

As far as the present material is concerned, the sequence between the vascular neof ormation and the subepithelial infiltration remains somewhat obscure.

Busacca's opinion that the vascularization is consequent upon development of the so-called avascular keratitis, and thus is to be regarded as a defense reaction against the invading virus, has already been pointed out.

Throughout the entire loupe examination, I have missed in a great majority of cases any signs on the cornea which might be ascribed to the process of a keratitis, although the subsequent infiltration following the incipient pannus is usually demonstrable even with the aid of a loupe, as seen in the foregoing descriptions. It would appear that at the very beginning stage of trachoma, at least, the vascularization takes place before any cellular in-

filtration becomes evident. However, this may prove to be deceptive because the loupe magnification is insufficient for detecting minute beginning changes which might possibly have taken place beneath the epithelium.

Another controversial point concerns the primary site of the vascularization process in relation to Bowman's membrane. Those who regarded the corneal infection as a contact infection once believed that vascularization first takes place under Bowman's membrane, leaving the epithelium more or less intact. Actually, however, the pannus vessels first creep between the epithelium and Bowman's membrane, indicating that it is the former which is primarily affected, analogous to the condition prevalent simultaneously on the conjunctiva.

The last strong evidence which speaks for the primary character of the corneal infection is clearly shown in the data presented in table 2. Here it is seen that the degree of pannus formation increases as the stage of trachoma advances. Whereas, incipient pannus appears uniformly in all stages of trachoma, the tenuis type is entirely absent in stage I, but increases to 4.66 percent and 25.71 percent in stages II and III, respectively.

This shows clearly that the trachoma infection attacks both conjunctiva and cornea at the same time so that the disease progresses simultaneously in both instances.

On the other hand, it is evident from the data of the same table, that pannus incipiens, although typically present in trachoma I (89.82 percent), is also found in stages II and III with the impressive incidences of 95.34 percent and 68.57 percent, respectively.

Apparently, pannus incipiens does not necessarily advance with the same speed of progression as do the conjunctival signs. Indeed, in its beginning stage, it

seemed to persist as the changes in the conjunctiva advanced. The explanation for this is most likely to be found in the role played by mixed infection. It is routine clinical experience that any preëxisting, nonspecific conjunctivitis constitutes a predisposing factor for contracting trachoma. Similarly, any trachomatous inflammation may be aggravated by a secondarily contracted, nonspecific mixed infection which causes acute inflammatory signs and thus obscures the actual stage of the specific disease. The mixed, infective agents, being nonspecific in nature, attack the conjunctiva primarily or exclusively, usually leaving the cornea free at the beginning stage. This leads to the apparent discrepancy between the two structures specifically involved.

Although the presence of mixed infection may influence the course of trachoma in the manner described, it is mainly the absence of mixed infection that has caused the predominance of beginning trachoma over the more advanced stages.

The better hygienic environment and personal cleanliness of student groups in general have already been taken into account. On the other hand, among trachomatous patients who live in unsanitary environments and have the undesirable habit of rubbing their itching eyes with dirty fingers, the incidence of mixed infection is astonishingly high.

Another clinical discrepancy not observed in the present series of data, but not infrequently encountered in one's daily practical experience, is the presence of a somewhat advanced pannus in association with a relatively harmless conjunctival manifestation.

This condition is often encountered in individuals of poor social and economic standing; in whom subclinical, nutritional deficiencies of some kind or other are bound to be more prevalent. One seems to

be justified in making the assumption that certain states of malnutrition (or undernutrition) may in some way contribute to the increased pannus formation of the cornea.

Nutritional research workers³ like Spies, Vilter, Ashe, Day, O'Brien, and especially Bessey and Wolbach, have established a clinical entity of the so-called "nutritional keratitis" as the earliest and most constant clinical manifestation of ariboflavinosis. This nutritional keratitis, which is characterized by superficial corneal vascularization from the upper corneal limbus, presents a picture of exactly the same morphology as that which describes incipient pannus. If it is too speculative to draw any conclusion from these purely morphologic similarities, it is, nevertheless, worth our closest attention and should be reserved as a problem for further investigation.

In this connection, it is interesting to mention the observation made by Victoria⁴ about an attenuated trachoma found endemically in northern Argentina. It is supposed to be a very mild type of trachoma, characterized by a slightly hyperemic conjunctiva and increase of limbal vascularization, with a few loops invading the cornea for a distance not greater than 1.5 to 2 mm.

This precisely confirms my own observations of trachoma in its very beginning stage, and it is evident that in so far as the pannus picture is concerned, we are both dealing with the same stage of the disease. The term "attenuated trachoma" is certainly misleading, because pannus incipiens is only a sign of the very early stage of trachoma which tends to progress and not of any independent category of the disease.

To sum up, then, one may say that trachoma is an infectious disease which affects both conjunctiva and cornea simultaneously, although certain local (mixed

infection) or general (undernutritional) conditions may aggravate one or another process so as to cause some discrepancy between the severity of conjunctival and corneal clinical signs. Pannus incipiens is the earliest detectable sign in the cornea, just as is subconjunctival infiltration in the conjunctiva.

The presence of neovascular sproutings from the upper limbal region into the transparent part of the cornea is, therefore, pathognomonic for the early stage of trachoma and may serve as a criterion for an early diagnosis of the disease.

The clinical application of incipient pannus in the diagnosis of beginning trachoma is to some extent, however, a circumstantial one. One or two sporadic vascular sproutings are not to be regarded as too significant. It is only when a large number of neovascular sproutings are present contemporaneously with coexisting conjunctival signs that a diagnosis of trachoma is justified.

Indeed, pannus plexus of extremely fine, delicate texture may persist long after trachoma I has healed without leaving even a trace of scarring on the conjunctiva. A diagnosis of beginning florid trachoma in such cases would certainly be a serious mistake.

Among the conjunctival signs, I lay more stress on the general haziness of the lower cul-de-sac, which is, to my mind, almost universally present as a result of subconjunctival infiltration and is, therefore, only secondary in importance to incipient pannus for the clinical diagnosis. A combination of incipient pannus with a more or less pronounced degree of peculiar haziness of the lower cul-de-sac guarantees the diagnosis almost with certainty. This is so even if the hypertrophic signs in the tarsal conjunctiva are so slight as to be almost absent.

SUMMARY

The difficulties in the diagnosis of beginning trachoma are discussed. A method for prompt, but decisive, diagnosis of the early stage of trachoma becomes urgent.

Careful examination of numerous beginning trachoma cases with a loupe under focal illumination usually reveals, in a very high percentage, positive neovascular sproutings from the pericorneal vascular loops of the upper overhanging limbus into the transparent part of the cornea. This condition is known as incipient pannus of trachoma.

Data from a mass of physical examinations of 2,370 marine volunteers are presented to substantiate the practicability of this clinical sign for the early diagnosis of the disease. It was found that 89.82 percent of the early trachoma cases showed positive incipient pannus formation, although a much higher percentage should be expected from a general, theoretical consideration, which suggests that the corneal infection of trachoma is of a primary nature and not the result of contact with an infected lid.

The infection of the conjunctiva and that on the cornea take up a parallel course of development, and incipient pannus is but an early sign of the corneal infection just as the subconjunctival infiltration is of the conjunctival reaction.

The primary nature of the corneal infection is indicated by: 1. The simultaneous appearance of the conjunctival and corneal changes. 2. The strict localization of the pannus vessels between the epithelium and Bowman's membrane. 3. The early involvement of the bulbar conjunctiva in the infection. 4. The fact that, as a rule, the degree of pannus formation increases as the stage of the trachoma advances.

Emphasis is placed upon the combined haziness of the lower cul-de-sac as indication of trachoma in its early stage.

EXOPHTHALMIC OPHTHALMOPLÉGIA AND ITS RELATION TO THYROTOXICOSIS

IDA MANN

Oxford, England

The classical signs of thyrotoxicosis include the ocular conditions of lid retraction and exophthalmos as well as the general effects of a raised basal metabolic rate, loss of weight, tachycardia, and tremor. The exophthalmos may be apparent only in life, disappearing on deep anesthesia or death, or may be real and persisting, when it should properly be called proptosis. In some cases there is also a disorder of function of some or all of the extrinsic ocular muscles (ophthalmoplegia), as well as edema of the lids and conjunctiva. The question is further complicated by the fact that proptosis and ophthalmoplegia may occur in a patient with none of the other signs of thyrotoxicosis, and, indeed, in patients whose basal metabolic rate is low, or whose thyroid glands have been partially removed prior to the appearance of any eye signs.

The experimental work of Marine and Rosen, of Smelser, and of Pochin, and the clinical observations of Russell Brain, Rundle, Mulvany, and others have done much to elucidate the problems of the relation of the eye signs to the endocrine imbalance and of the gradations, combinations, and varieties of exophthalmos, proptosis, lid edema, ophthalmoplegia, and altered basal metabolic rate which may occur in man.

The discovery of the thyrotropic hormone of the pituitary marked the beginning of the rational comprehension of the interaction of the thyroid and the pituitary in the production of these varying ocular complications. The linkage of animal experiment to clinical findings and to treatment is still, however, incomplete, and the present series of patients is shown in an attempt to clarify the still outstanding problems and to indicate how far the experimental work can be of use in interpreting individual cases.

As Marine and Rosen (1934) and Smelser (1936) pointed out, both exophthalmos and proptosis can be produced experimentally. Widening of the palpebral aperture and slight protrusion of the eye can be produced in many animals by any agent which stimulates smooth muscle. It is transient and disappears on anesthetizing or killing the animal. It is prevented by removal of the cervical sympathetic. These experiments in part explain the lid retraction and staring look of thyrotoxic patients, who do not show proptosis or ophthalmoplegia. That proptosis in man is not to be explained in this way has been pointed out by Russell Brain and illustrated by a case in which proptosis developed in a patient with paralysis of the cervical sympathetic from a pre-

vious syringomyelia. Smelser further pointed out that extracts of the anterior lobe of the ox pituitary produced a true proptosis (persisting after death) in guinea pigs from which the thyroid glands had been previously removed. He has followed up these observations with experiments extending over eight years and has obtained results of great importance. These may be summarized:

If a series of guinea pigs be subjected to thyroidectomy and to unilateral removal of the cervical sympathetic ganglion so as to produce a slight unilateral ptosis, and then injected with extracts of ox anterior-lobe pituitary or Antuitrint, it will be found that proptosis develops to an equal extent on both sides. This proptosis may be slightly masked on the one side by the drooping lid, but after death and removal of the lids and skin of the head it is seen to be equal on the two sides and to be directly due to increase of the orbital contents.

Estimation of the constituents of the orbital contents shows the increase to be 100 percent in the fat, 40 percent in the dorsal lacrimal gland, and 22 percent in the extrinsic muscles. Further investigation shows that the water content of all these tissues is much increased. If the orbital fat alone is examined no increase in lipid content will be demonstrated, but a connective-tissue hyperplasia and edema will be found to account for the 100 percent increase in the fatty tissue. Similarly, edema and round-cell infiltration of the muscles will account for their increase also. Smelser has shown that this process of connective-tissue hyperplasia and water retention is not, in the guinea pig, confined to the orbital fat but also involves other body fats, originally rich in connective tissue, such as the retroperitoneal, paraovarian, and paraureteral fat, but not the subcutaneous fat, where the connective tissue is sparse. Increase in bulk

of these fats will naturally be apparent only in the orbit, where the walls are rigid and expansion can only take place in one direction.

The condition of the extrinsic ocular muscles is interesting, and a certain amount of doubt still exists as to whether changes in the muscle fibers themselves are present in all cases, as Mulvany suggests, or whether they are merely secondary to the edema and small round-cell infiltration.

It would appear that in guinea pigs, at least, the increased water content of the orbital tissues is primary, and the hypertrophy of the muscles secondary. If one eye is excised at the beginning of the experiment, the contents of the orbit increase equally on both sides, but the muscles do not hypertrophy on the anophthalmic side. On the other hand, if proptosis is produced by entirely different means in intact guinea pigs (as by a uterine graft behind the eye made to hypertrophy by estradiol benzoate), the muscles hypertrophy in response to the pushing forward of the eye, but there is no increase in the water or fat content of the whole orbit.

These experimental results have been in part confirmed on human material, which shows similar histologic changes in the connective tissue of both orbital fat and lid subcutaneous tissue, and rather more change (hypertrophy and fragmentation) in the muscles, with late secondary fibrosis in cases of long standing.

The effects described in guinea pigs are undoubtedly due to excess of the anterior-lobe pituitary secretion, since the thyroids had been removed. The effects of excess thyroxine in guinea pigs are entirely different. Proptosis is never produced. The animal loses weight, and there is finally enophthalmos from absorption of orbital fat. Marine and Rosen, how-

ever, consider that sympathetic stimulants, which produce lid retraction and transient exophthalmos from contraction of smooth muscle, act more readily in the presence of excess thyroxine. This may be due to sensitization of unstriated muscle by the thyroxine, or associated with a myasthenic weakness of striped muscles as described by Mulvany.

It therefore seems likely that, clinically, we should be able to distinguish these various primary and secondary effects of excess pituitary thyrotropic hormone from the effects of excess thyroxine and possibly coincident excess adrenalin acting on thyroxine-sensitized structures or against thyroxine-weakened antagonists.

We are looking for three sets of eye signs; namely, signs of overaction of unstriated muscle (lid retraction and exophthalmos abolished by anesthesia), signs of weakness of striped muscle (ophthalmoplegia), and signs of increase in bulk (water retention) in the orbital and lid tissues (proptosis; chemosis and edema of lids). General changes due to excess or deficiency of thyroxine (raised or lowered basal metabolic rate and loss or gain in weight) may also complicate the picture.

In addition, in man, we are confronted by the possible action of the central nervous system acting through the hypothalamic structures as the stimulant or depressor of the pituitary. This aspect must always be remembered. Its importance was pointed out by Russell Brain in 1936, when he stated that, in the majority of his patients with exophthalmic ophthalmoplegia, there was a history of mental shock or emotional strain from extrinsic causes. Purely psychogenic sources of emotional disturbance were conspicuously absent.

The assumption has been made by Mulvany, from observation of clinical material and pathologic examination of

orbital tissues in man, that two completely distinct conditions exist: one due purely to excess of thyroxine, the other due to excess of anterior-lobe pituitary hormone. This latter will, under certain conditions, lead to excess thyroxine by stimulation of the thyroid gland, if this is capable of responding. He designates the first condition "thyrotoxic ophthalmoplegia" and the second "thyrotropic exophthalmos."

In thyrotoxic ophthalmoplegia there is weakness of extraocular muscles accompanied by spastic contraction of the unstriated muscle of the lids and orbit from overaction of the sympathetic (possibly sensitization to adrenalin by the thyroxine). This leads to retraction of the upper lid, exophthalmos which can be at least partially reduced by steady pressure on the globe, and some weakness of muscular action (ophthalmoplegia). There is no increase in orbital contents, no edema of the lids, nor enlargement of the lacrimal gland. The lids are soft and flaccid and the eyeball moves freely when palpated in the socket.

In thyrotropic exophthalmos, on the other hand, Mulvany considers that excess anterior-pituitary hormone produces marked structural changes in the striped muscles of the orbit as well as true increase in volume of the orbital contents, with severe edema of the lids, orbital contents, and conjunctiva. Ophthalmoplegia as well as proptosis results, and the eyeball cannot be pressed back nor moved freely about in the orbit.

According to Mulvany, degenerative change in the striped muscles is produced by an excess of thyroxine alone, and this change can be distinguished microscopically from the fibrosis and edema of these muscles produced by excess thyrotropic hormone. It is, however, difficult to accept the two appearances as separate pathologic entities, since fibrosis would be

the predicted end result of the changes ascribed to excess thyroxine.

It seems more likely that the degeneration is a continuous process, due solely to the pituitary hormone but capable of coexisting with the effects of excess thyroxine (contraction of smooth muscle and wasting of orbital fat) and clinically somewhat masked by them. It is well known that in thyrotoxicosis, as from a thyroid adenoma, there may be a high basal metabolic rate (B.M.R.), loss of weight, tachycardia, sweating, and tremor, but no ophthalmoplegia; whereas, in cases of excess thyrotropic hormone with a low B.M.R. there is practically always some ophthalmoplegia. Clinically, however, in most cases of raised B.M.R. (thyroxine excess) not associated with thyroid adenoma, there is a pituitary element manifesting itself as edema of the lids and weakness of some or all of the eye movements. It is, therefore, simpler to look on lid retraction as a sign of excess thyroxine and defective eye movement (which actually may be present without proptosis) as resulting from excess thyrotropic hormone.

The present series of cases has been studied in an attempt to disentangle the parts played by the thyroid and the pituitary, respectively, in individual patients, and it is hoped to show that the two conditions described by Mulvany and produced experimentally may coexist or overlap. The 18 cases are grouped on the presumptive evidence of the probable single or multiple endocrine disturbance underlying them. Purely thyrotoxic cases have not been included, as the problem has been tackled chiefly from the pituitary point of view.

The cases seem to fall into three groups:

Group I. Primary deficiency of thyroxine with compensatory excess of thyrotropic hormone secretion (4 cases).

Group II. Primary excess thyroxine as initial symptom followed by thyroid atrophy or removal, replaced by excess thyrotropic hormone (10 cases).

Group III. Excess thyroxine and excess thyrotropic hormone arising simultaneously (4 cases).

CASE REPORTS

GROUP I. PRIMARY THYROXINE DEFICIENCY WITH COMPENSATORY EXCESS THYROTROPIC HORMONE

Three women and one man fall into this group. They were all between 50 and 60 years of age (average 54). One patient gave a history of fright in an air raid and one of overwork. The other two could assign no cause and were not neurotic personalities.

In all four patients there was edema of the lids and, in three, of the conjunctiva also. The lids appeared puffy, stiff, and showed poor movement. In three cases the lids could not be completely closed, but lid retraction was not present, and the appearance did not suggest thyrotoxicosis. The patients' skin was sallow, thick, coarse, and slightly suggestive of myxedema. The proptosis (in three) could not be reduced by pressure, and the B.M.R. in the three cases in which it is known was subnormal (—9 percent; —27 percent; and 0 to —1 percent). In two of the cases one eye was lost from exposure before I saw the patient, but the other eye was saved by tarsorrhaphy and excision of conjunctiva, the patient being put on thyroid extract until the B.M.R. was well raised. One case was seen very early and required no local treatment. In the fourth case there was partial tarsorrhaphy, and the patient's eyes were saved, although she showed many anomalous features and her early history is obscure.

Case 1. Miss E. G., aged 54 years (figs.

Figs. 1-4 (Mann). Group I, Case 1, Miss E. G., aged 54 years. Fig. 1, the patient on October 23, 1942. B.M.R., -27. Note the edema and pouching of the lower lids, the slight fullness above the eyes with commencing overhang of the tissues of the upper lid. There is no lid retraction, but the left eye is slightly more prominent than the right and the upper lid more swollen. Fig. 2, same date, showing the lids from the side. The edema is obvious, although not yet excessive. Fig. 3, the patient on January 29, 1945—B.M.R., +12—after treatment with 2 gr. thyroid extract per day. The edema of the lower lids has completely disappeared and the skin crease in the upper lids is now raised. Fig. 4, same date as in figure 3, shows the side face. Comparison with figure 1 demonstrates the disappearance of the edema. The left eye is now more widely open, as the lid is not so heavy.

1, 2), presented the earliest case observed in the series and was diagnosed and treated before the signs of compensatory pituitary activity became at all marked. The patient stated that since coming to live in High Wycombe, four years previously, she had felt "old and tired." Her skin had become dry, and she noticed extremes of temperature more than heretofore. Her eyelids, especially the lower lids, had become very puffy during the last year. She appeared somewhat slow and depressed in manner. Her color was good, but the skin below the lower lids was edematous and pouched. The left eye was slightly more prominent than the right. There was no limitation of movement. She showed early senile cataract. Vision was 6/12 with correction of low myopia. There was a small choroidal scar in the fundus of the left eye.

The patient was 5 ft. 4 in. in height; weighed 119 lbs. Her pulse rate was 80, and the B.M.R. -9 percent.

The clinical evidence appeared to be against myxedema. (She was mentally alert and not markedly gaining in weight.) She was treated with thyroid extract (2 gr. per day) and reported after six months that she felt "a new woman," and that all the swelling of the lids had disappeared. The skin of the lids was soft and normal, and the proptosis of the left eye had disappeared (figs. 3, 4). Her B.M.R. was +12, and the pulse 80. She has continued well on this dose of thyroid for two years.

Case 2. Mrs. B. P., aged 54 years, was well until 1941, when she was badly frightened in an air raid. A fortnight after this her eyelids began to swell and her eyes to protrude. In two months she became unable to close them completely, and the cornea of the left eye ulcerated. Her skin was dry and her pulse slow.

The patient was 5 ft. 1 in. in height and

weighed 120 lbs. Her pulse rate was 80, and her B.M.R. -27 percent.

She developed a hypopyon ulcer in the left eye, and this eye was excised. After excision of the eye, the tissues in the socket continued to increase and bulged slightly between the lids. (This is reminiscent of Smelser's aforementioned observations on guinea pigs.) The right eye became increasingly proptosed, and there was limitation of upward and downward movement. Eight months after the air raid, she was admitted to the Oxford Eye Hospital and treated by tarsorrhaphy of the right lids and 3 gr. of thyroid extract a day. In three months her weight had dropped to 105 lbs. and her B.M.R. was +14 percent; pulse 64. She stated that she felt very well. The eye movements had improved, the proptosis was less, and vision was 6/12. She was advised to continue the thyroid but to decrease the dose slightly. She attended four months later, having gained two pounds in weight, when the B.M.R. was -4 per cent. She appeared well, but will probably have to continue on thyroid extract indefinitely. She appears to have been an early thyroid failure in whom fright had produced an excess of anterior-pituitary secretion, but no coincident increase of thyroxine, as a relatively large dose of thyroid was required to raise her B.M.R.

Case 3. Mr. F. A., aged 57 years, had to work overtime in very bad conditions from March, 1941. He noticed some fullness of his neck and puffiness of both upper and lower lids, but no protrusion of the eyes. Soon after this he complained of double vision. In September, 1941, he was admitted to the Oxford Eye Hospital (fig. 5). The patient was 5 ft. 6 in. in height and weighed 149 lbs. His pulse rate was 60, and his B.M.R., 0. He was a pale, rather stout man, with thickened skin and heavy features, sug-

gestive of myxedema. All four lids were edematous, brawny, and immobile. There was complete external ophthalmoplegia, but practically no appearance of proptosis. As the eyes and lids were immobile, there was no protection of the corneas in sleep, and the right eye had a severe, perforated hypopyon ulcer. Vision of the left eye was 6/9. The brawny swelling of the lids could be reduced by massage, but

was then put on 3 gr. of thyroid extract a day, when he began to improve rapidly and was discharged. He decreased the thyroid extract, and, on readmission, two months later, his weight had increased to 170 lbs. and his B.M.R. was -1 percent, his pulse rate 60. He has since been stabilized on 1 gr. of thyroid extract a day. His weight is 157 lbs., his B.M.R. +3 percent, and his pulse 50 (fig. 7). The

Figs. 5-7 (Mann). Group I, Case 3, Mr. F. A., aged 57 years. Fig. 5 shows the patient on September 17, 1941. B.M.R., 0. The edema of the lids is extreme, and there is complete loss of movement of the eyes and lids. The eyes cannot be closed, and the right cornea has perforated from exposure. The patient's skin is coarse, and the general appearance should be compared with figure 26, which shows a very similar facies in a woman. Fig. 6 shows the patient on November 7, 1941, after removal of the right eye and of redundant edematous tissue from the lids. Massage has been employed freely after healing. He has not yet been treated with thyroid. Fig. 7, the patient on January 27, 1945, after treatment with 3 gr. thyroid extract per day, reduced subsequently to 1 gr. The skin of the lids is now soft, and the eye movements are improving. He has been fitted with an artificial eye and both eyes are now closed during sleep.

they could not be made to close. The eye appeared firmly imbedded and could not be made to move in the orbit on palpation.

Operation was performed for excision of the right eye, and partial tarsorrhaphy of the left lids, combined with a plastic operation on the upper lids in which the redundant folds of edematous skin were removed, and also portions of orbital tissue from the socket. Sections of all these showed extreme edema and slight connective-tissue proliferation. The operation wounds healed and the condition of the lids improved under frequent massage (fig. 6). His visual acuity, however, dropped to 6/36, and a patch of exudate appeared at the macula of the left eye. His weight increased to 162 lbs. in the two months following the operation. He

eye movements have improved, the macula is now normal and vision 6/6. He is doing full work and feeling very well. He resembles the previous case in that a period of strain was met by increased anterior-pituitary hormone, the thyroid failing to respond. It is interesting to note that the complete ophthalmoplegia and intense edema were not accompanied by much evident proptosis.

Case 4. Mrs. M. E. D., aged 47 years, presented a very complicated and anomalous case, but was placed in this group on account of the fact that the presenting symptom was gain in weight and presumptive early myxedema. The history was complicated by an attack of poliomyelitis at the age of 22 years, which left the patient unable to take much exer-

cise. I did not see her in the early stages of her later illness myself, but she stated that in 1938 she was treated for increasing obesity by thyroid extract. This was stopped; her eyelids then became swollen, and she was advised to have her thyroid gland removed. After the operation she developed severe proptosis, with complete paralysis of both internal recti, swelling of the lids, and chemosis. I saw her in 1940, and performed bilateral partial tarsorrhaphy. An attempt was made to treat her with thyroid extract, but she felt very ill and it was discontinued. She remained fairly well, but the proptosis remained and some limitation of movement until 1943 (but with good visual acuity—R.E. 6/9; L.E. 6/6), when she suddenly developed severe myasthenia gravis. This responded at the time to prostigmine, but she since relapsed and died of respiratory failure, a thymus tumor being found *post mortem*. The eye condition remained stationary, though she could not close her lids, owing to facial weakness, not to proptosis. This would appear to have been a case of primary thyroid failure, probably made worse by thyroidectomy and complicated by thymus tumor, but the early history of the case is obscure and exact data, including the B.M.R., are not available.

GROUP II. CASES IN WHICH THE PRESENTING SYMPTOMS SUGGEST EXCESS THYRONINE FOLLOWED BY THYROID FAILURE OR THYROIDECTOMY AND SUBSEQUENT EXCESS THYROTROPIC HORMONE.

Ten cases fell into this group, eight in women and two in men. Their ages ranged from 44 to 76 years, distributed thus: 44, 47 (2), 54, 56, 57, 60, 62, 71, 76. In seven cases there was a definite history of shock or mental strain followed by symptoms of hyperthyroidism. In three there was no history other than the usual complaint of overwork and war

anxiety. Of the seven cases in which there was a definite history, the shock in five was connected with the war; personal experience in air raids (2), death or injury of near relation (2), hardship over billettees (1). The sixth case was that of personal worry over a criminal member of the family, and the seventh, the shock of an operation for strangulated hernia. In two of these cases, there was a previous breakdown with tachycardia and loss of weight, following, in one case, a motor smash and, in the other, the death of a husband. In them all the history was of an illness characterized by loss of weight and tachycardia, followed either by recovery or thyroidectomy. Swelling of the lids, proptosis, and ophthalmoplegia then developed, sometimes after a second shock, sometimes independently. Six of the 10 patients had had a thyroidectomy with improvement, immediate but not maintained. The time elapsing between the thyroidectomy or the spontaneous remission of the tachycardia and the appearance of ophthalmoplegia varied from 14+ years in two cases, with history of second shock, to a few days in some of the thyroidectomized patients.

Case 1. Mrs. E. C., 44 years, had had attacks of tremor, tachycardia, and loss of weight but no proptosis in 1913, 1920, 1928, and 1941. All except the last were relieved by rest and sedatives. Thyroidectomy was performed in 1941, and was followed by tetany and proptosis. Within a month of the operation the eyes could not be closed, and there was ophthalmoplegia (fig. 8). The patient weighed 133 lbs., her B.M.R. was +3, her pulse 80, and visual acuity: R.E. 6/60, L.E. 6/24.

Bilateral tarsorrhaphy was performed, and the patient was put on 2 gr. of thyroid extract per day and calcium gluconate. In seven months her weight had decreased to 121 lbs., and the B.M.R. rose to +23.

Figs. 8-10 (Mann). Group II, Case 1, Mrs. E. C., aged 44 years. Fig. 8 shows the patient on September 24, 1942. B.M.R., +3. Thyroidectomy performed in 1941. This photograph was taken after a complete tarsorrhaphy in the right eye and a partial in the left. The lids are under some tension and the edema is obvious at the inner canthus. Fig. 9 shows the patient on June 25, 1943, after treatment with 2 gr. thyroid extract per day, and calcium gluconate. The B.M.R. is now +23, the lids are no longer tense, and the tarsorrhaphies have been partially reopened. Convergence has returned almost completely. Fig. 10 shows the patient on May 3, 1944, stabilized, with a B.M.R. of +12 and tarsorrhaphies further reopened. The movements of the right eye are full. Those of the left slightly restricted outward. Further reopening of the tarsorrhaphies can now be done as there is no edema of the lids and the proptosis is disappearing.

The patient felt much better, convergence returned, and visual acuity rose to R.E. 6/9, L.E. 6/12 (fig. 9). The fundi were normal. Two years after the tarsorrhaphy the condition was stabilized with a B.M.R. of +12, pulse 72, weight 123 lbs., and visual acuity of 6/6 right and left. The movements of the right eye were full, those of the left slightly restricted outward (fig. 10).

Case 2. H. W., a man, aged 47 years, had had a thyroidectomy in 1934. Proptosis had slowly increased since that time. He was treated for corneal ulcer in February, 1944. His height was 5 ft. 6 in., his weight 157 lbs., B.M.R., -10 percent, and pulse 84.

He was treated with 3 gr. of thyroid extract a day, and the eyes improved. Now he remains well on 1 gr. a day. The eyes are practically normal.

Case 3. Mrs. E. H., aged 47 years (fig. 11) had had a thyroidectomy in

1941. After a succession of war and family worries her eyes began to swell

Fig. 11 (Mann). Group II, Case 3, Mrs. E. H., aged 47 years, photographed on November 7, 1944. B.M.R., 0. Thyroidectomy in 1941. The patient had noticed protrusion of the eyes and puffiness of the lids, especially at the inner canthi, for two months. The photographs show the protrusion of the globe and the beginning edema, especially on the right, involving the upper lid at the inner end and also commencing below the lower lid. Compare figure 2, which shows edema in the same position, but without proptosis.

in September, 1944 (fig. 12). By March, 1945, there were severe chemosis, lid edema, and proptosis. The patient was feeling ill and complaining of gross defect in vision—R.E. less than 6/60; L.E. 6/12. There was some ophthalmoplegia (figs. 13, 14). The patient's height was 5 ft. 5 in.,

Case 4. E. S., a woman aged 54 years, had thyrotoxicosis after a motor accident many years ago, but recovered on rest. Three months ago she had much worry with billettees, and her eyes began to protrude. The B.M.R. was +58 percent. The patient's appearance indicated a typi-

Figs. 12-14 (Mann). Fig. 12, same case as in figure 11, shows patient on January 10, 1945. The swelling has increased enormously and the edema of upper and lower lids is marked. The conjunctiva is injected. The patient's skin is becoming coarser and she is gaining weight. Fig. 13 shows the patient on March 8, 1945. She has been treated with rest but has become steadily worse. There is gross edema, proptosis, and eversion of the lower fornix, which is partially strangulated by the lower lid. Fig. 14, same date, shows the condition on closing the eyes. The corneas are protected, but the conjunctiva is exposed. Thyroid treatment was commenced at this point.

her weight 128 lbs., her B.M.R., 0, and her pulse 68.

She was put on rest, 1 gr. of thyroid extract a day, and phenobarbitone. The condition grew steadily worse, and proptosis of the lower fornix occurred, necessitating tarsorrhaphy and excision of redundant conjunctiva on two occasions. The patient is still very ill and has gross field defects, but is definitely showing improvement. The dose of thyroid which gives the best results in 2 gr.*

* Since this paper was sent in for publication, this patient has continued to improve. The chemosis has subsided, the tarsorrhaphies have been reopened, and visual acuity is R.E. 6/24; L.E. 6/9. She is now living at home and doing most of her housework, after an illness of about a year.

cal thyrotoxicosis, but there was limitation of upward movement of both eyes

Fig. 14A (Mann). Mrs. E. H. five months after tarsorrhaphy of R.E. and thyroid treatment.

and proptosis. Thyroidectomy was performed in March, 1945. She is now feeling much better, but the proptosis is slightly worse. It appears that even before operation there was excess thyrotropic hormone, and it is doubtful whether this case will progress or not since the source of her worry has been removed.

Case 5. M. H., a woman, aged 56 years, had a thyrotoxicosis after a motor accident in 1927, with complete recovery on rest. In 1940, she was bombed and also very worried over a son in the army. Her lids swelled and her eyes became prominent soon after. A B.M.R. of +13 percent and a high blood-sugar curve were found. Ophthalmoplegia and diplopia developed, but never became excessive; after prolonged rest and treatment with aminophyllin the patient returned to full work and reported no diplopia (except

on extreme abduction) and no difficulty in closing the eyes.

Case 6. Mrs. D. D., aged 57 years, in five months lost 56 lbs., with sweating and palpitation, not associated with mental shock (weight then 98 lbs.). Thyroidectomy was performed. The eyes became more prominent soon after and remained so for four years, when she attended the Oxford Eye Hospital because of the discomfort from them (figs. 15, 16). Her height was 5 ft. 3 in., her weight 143 lbs., the B.M.R. -4, and pulse rate 64.

She was put on 2 gr. of thyroid extract a day, and immediately noticed improvement in the eyes. This dose was too large, and she began to lose weight rapidly. Vision was 6/5; the eyes prominent, but mobile. She is at present being stabilized.

Case 7. Mr. J. D., aged 60 years, in 1941

Figs. 15, 16 (Mann). Group II, Case 6, Mrs. D. D., aged 57 years. Fig. 15 shows patient on February 14, 1944. B.M.R., -4. Thyroidectomy performed four years previously. Note the fullness of the upper and lower lids and the overhang of the upper lid, which masks the proptosis (see Fig. 16). The eyeballs are prominent, but there is no lid retraction. Fig. 16, same date, shows fullness of upper lids but normal palpebral aperture in spite of proptosis.

Figs. 17, 18 (Mann). Group II, Case 7, Mr. J. D., aged 60 years. Fig. 17 shows patient on March 10, 1944. B.M.R., +29. This patient has not had a thyroidectomy, but is gaining weight. Note commencing proptosis with edema of upper lids. Fig. 18, same date showing overhang of upper lids but widened palpebral aperture. The B.M.R. is still raised, and lid retraction is therefore present as well as edema.

had vision of R.E. 6/6, L.E. nil (optic atrophy). This patient had an operation for strangulated hernia in June, 1942. He began to lose weight and went down to 109 lbs. In December, 1943, he had tachycardia, tremor, and commencing exophthalmos. By March, 1944, he had recovered largely from the tachycardia and tremor and was gaining weight, but the proptosis was increasing and there was ophthalmoplegia (figs. 17, 18). His height was 5 ft. 6 in., his weight 115 lbs., B.M.R. +29 percent, and pulse rate 90. Visual acuity, R.E., was 6/24.

A lateral tarsorrhaphy was performed. The patient improved on rest alone. His B.M.R. dropped to +27 and pulse to 76. Vision improved to 6/18, and he returned to work.

Case 8. Mrs. M. E., 62 years, had a great deal of family worry during 1941-42 and wept a great deal. She lost weight and her eyes watered, but did not become prominent until her thyroidectomy in

1944. She was in hospital a fortnight, and immediately upon returning home her eyes began to protrude. Within two months both eyes became grossly proptosed with ulceration and perforation of the left cornea and chemosis so great that the whole conjunctiva was everted and the lids could not be closed in either eye (figs. 19, 20). Complete ophthalmoplegia and edema of the lids were also present. She was admitted to the Oxford Eye Hospital. The patient's height was 5 ft. 3 in., her weight 110 lbs., her vision, R.E., was ability to count fingers at 2 ft. (veins very engorged); L.E., no light perception. The patient was too ill for B.M.R. estimation, but was gaining weight.

Operation was performed by Mr. Houlton: evisceration of the left eye and plastic operation on right and left eyes for removal of redundant conjunctiva and closure of lids. The patient was put on thyroid extract, gradually increased to 4 gr. a day (fig. 21) and reduced again finally to 0.5 gr. a day during the ensuing

Figs. 19-23 (Mann). Group II, Case 8, Mrs. M. E., aged 62 years, was photographed on June 1, 1944. B.M.R., +2. She had had a thyroidectomy in April, 1944. Fig. 19 shows gross edema of the lids, particularly at the inner canthi, and total eversion of the conjunctiva in the left eye, eversion of the lower fornix in the right. The cornea of the left eye is beginning to ulcerate. Fig. 20, same date, shows the patient from the left side with gross chemosis. Fig. 21 shows the patient on August 3, 1944, after treatment with thyroid extract gradually increased to 4 gr. per day, combined with excision of the left eye, partial tarsorrhaphy on the right, and removal of redundant conjunctiva. The orbital contents on the left continued to protrude after removal of the globe. Fig. 22 shows the condition on January 13, 1945. B.M.R., +2. The edema of the lids and the chemosis have disappeared. The contents of the left socket have receded, and the patient is looking much better. Fig. 23, same date, shows profile from the right side and demonstrates that there is now very little edema or proptosis.

eight months. A further tarsorrhaphy on the right eye became necessary and was successful. This eye was partially re-opened as the patient improved. Nine months after admission she reported fit and well, doing all her house work (figs. 22, 23).

Her B.M.R. was +2 percent, her pulse rate 74. Vision in the right eye was 6/24;

the fundus normal.

Eye movements are practically normal and chemosis and lid swelling have disappeared.

Case 9. Mrs. R. C., aged 71 years, had a history of a breakdown with loss of weight after the death of her husband, about 1920. In 1941, she became worried

about her son in the R.A.F. He was injured in 1943. In 1944, she was badly frightened by a motorcycle accident. She had been losing weight until then, and in 1944 her lids became edematous and her eyes prominent. There was slight limitation of movement and no gross chemosis, but swelling of the lids (figs. 24, 25). The retinal veins were full and there were

tivity in thyrotropic hormone production.

Case 10. Miss E. P. S., aged 76 years, made no complaint about her appearance, but stated when questioned that in 1940 she had had an attack of thyrotoxicosis which might have followed the bombing of her home. She was not certain of the sequence of events, but did not feel worried. Her eyes began to protrude; in 1941

Figs. 24, 25 (Mann). Group II, Case 9, Mrs. Rose C., aged 71 years, was photographed on November 21, 1944. B.M.R., +25. The patient had been losing weight since 1941, and in 1944 her lids became edematous. Fig. 24 shows the overhang of the upper lid, and the fullness of the whole orbit and contents. Fig. 25, same date, shows a slight lid retraction on the right, but on the left side the proptosis is masked by the overhanging lids.

two small choroidal scars. Vision was 6/6 with each eye. She was thin and appeared slightly thyrotoxic and was therefore put on phenobarbitone. Her weight was 91 lbs., her B.M.R. +25 percent.

She has remained well for six months, but there is more limitation of upward movement of the eyes. Hers would seem to be a case in which a thyrotoxicosis is subsiding spontaneously and is now giving place to symptoms of an increased ac-

she began to gain in weight, and her appearance suggested myxedema. She was put on 0.5 gr. thyroid extract per day and remained well.

She attended the Oxford Eye Hospital in 1942, with very defective eye movements, puffy lids, and proptosis (figs. 26, 27). Her weight was 149 lbs., B.M.R. -7 to -10 percent, her pulse rate 75, and vision with each eye 6/18 (high myopic correction).

Thyroid treatment was continued and increased to 1 gr. daily. The patient feels very well. Her vision has improved to R.E. 6/9; L.E. 6/12, and all eye movements have returned except that of the

mos in two cases. The B.M.R. in three was high (+38, +42, and +43 percent); in the fourth it was not tested before treatment. On this account they could not be given thyroid extract and were all

Figs. 26, 27 (Mann). Group II, Case 10, Miss E. P. S., aged 76 years, was photographed on October 23, 1942 (Fig. 26). B.M.R., -10. Gain in weight following mild attack of thyrotoxicosis two years previously. Her appearance should be compared with figure 5. Her skin is coarse and there is marked edema of the lids and overhang of the upper lid. There is limitation of ocular movements and proptosis, though this is masked by the lid edema. Fig. 27, same date, shows profile from the left side and demonstrates the edema of the orbital contents. The eye movements have since returned on treatment with 1 gr. thyroid extract per day.

left external rectus muscle, which is improving.

GROUP III. EXCESS THYROXINE AND EXCESS THYROTROPIC HORMONE ARISING SIMULTANEOUSLY.

Four cases fall into this group, in three men and one woman, aged, respectively, 42, 53, and 60 (2). Two gave a history of war experiences (shipwreck and bombing), and two of overwork in civilian life. In all four the symptoms were loss of weight, tachycardia, proptosis, and ophthalmoplegia, all coexistent, the loss of weight slightly preceding the exophthal-

mos treated differently on their individual merits.

Case 1. Capt. D. de C., aged 42 years, was torpedoed and shipwrecked. There followed loss of weight, severe proptosis, almost complete ophthalmoplegia, and corneal ulceration of the right eye (figs. 28, 29). The skin was moist, and there was a fine tremor. The patient felt very ill and anxious.

He was first treated with progynon, which made him feel ill, as did also Lugol's solution, which increased the chemosis. After a bilateral tarsorrhaphy, in-

Figs. 28, 29 (Mann). Group III, Case 1, Capt. D. de C., aged 42 years, was photographed February 18, 1943. B.M.R., ?. Fig. 28 shows gross edema of the whole orbital contents and proptosis. The skin is moist, and there are signs of thyrotoxicosis. Fig. 29, after central tarsorrhaphy on the left. The edema is still greater on the left.

jections of testosterone were begun. After the fifth, he reported very great improvement in subjective sensations and greater comfort in his eyes. Twelve months after the beginning of his illness, he had returned to sea, having improved steadily. He reported, 12 months later, that he was doing full work, feeling well. His B.M.R. was now +10 percent, but he had rather prominent eyes.

Case 2. Mr. T. F., aged 53 years, was working hard but had always been nervous. In 1941 he lost weight, and noticed double vision. Within a year he was referred to the Oxford Eye Hospital with

bilateral proptosis, ophthalmoplegia, and eversion of the conjunctiva (figs. 30, 31). He stated that he had begun to gain slightly in weight, but that his eyes were becoming more prominent and fixed. His weight varied between 105 and 120 lbs. over a period of six months. His B.M.R. was +38 percent, his pulse rate 100. Vision was R.E. 6/24, L.E. 6/9. There was severe engorgement of the retinal vessels with papilledema.

Bilateral tarsorrhaphy and excision of prolapsed conjunctiva were performed (figs. 32, 33). The patient became very ill, anxious, and restless. Five weeks later he discharged himself and returned home.

Figs. 30-34 (Mann). Group III, Case 2, Mr. T. F., aged 53 years, was photographed January 27, 1942. B.M.R., +38. Fig. 30 shows gross edema of lids, orbital contents, and conjunctiva, with retraction of the upper lid, as he is still thyrotoxic. Fig. 31, same date, shows patient with the eyes closed. Compare this with figure 14.

Fig. 32 shows the patient on March 19, 1942, after partial tarsorrhaphy and removal of excess conjunctiva. Fig. 33, same date, shows the protrusion of the orbital contents.

Subsequent reports show that he rested at home without treatment for some time and then had a course of deep X-ray therapy to the pituitary. He improved markedly. His weight rose to 134 lbs. and his B.M.R. decreased to +22 percent. Visual acuity improved to R.E. 6/9 and L.E. 6/5; the papilledema subsided. The eye movements remained limited and there was diplopia, which prevented his return to work (fig. 34).

Fig. 34, the patient on December 14, 1944, after treatment by prolonged rest and deep X-ray to the pituitary. The eye movements have partially returned, but he still has diplopia. The edema has subsided. Conjunctiva is normal.

Case 3. J. P., a woman aged 60 years noticed loss of weight, breathlessness, and tachycardia with protrusion of the eyes after being in the London blitz in 1940. She lost 28 lbs. within a year. Her pulse rate was 120, the B.M.R. +32. Her skin was moist, and she had exophthalmic ophthalmoplegia.

A bilateral tarsorrhaphy was performed; a month later partial thyroidec-

tomy. A year later she returned, feeling very well. Vision, R. and L., was 6/6, and the eyes were practically normal. The tarsorrhaphies were undone with a very good result, only a slight von Graefe's sign remaining. In this case, the removal from London and consequent relief from anxiety together with partial thyroidectomy seem to have aborted the excess anterior-lobe pituitary function, and the condition appeared stabilized a year later.

Case 4. A. B., a man aged 60 years, in 1942 was subjected to severe overwork and strain in his business. After a year, he developed a fine tremor, and others noticed that his eyes were prominent, especially the right. In 1944, he came to Oxford (figs. 35, 36). His weight was 144 lbs., his pulse rate 72, and the B.M.R. +43. External ophthalmoplegia and proptosis were present.

A lateral tarsorrhaphy was performed, and the patient was treated with progynon. He improved slightly and gained 16 lbs., but a few months later broke down again and developed auricular fibrillation. The eye movements had recovered, and there was very little proptosis. Von Graefe's sign and lid retraction were marked, and his condition suggested excess thyroxine, with practically no pitui-

Figs. 35, 36 (Mann). Group III, Case 4, Mr. A. B., aged 60 years was photographed on August 30, 1944. B.M.R., +43. In Fig. 35 the patient exhibits the signs of pituitary exophthalmos and of thyrotoxicosis. There is edema of the lids (especially above the inner canthus of the upper lids); also lid retraction and limitation of movement. Fig. 36, same date, shows the right side and demonstrates the overhang of the upper lid coexisting with lid retraction and proptosis.

tary disturbance. His condition is at present being treated with thiouracil and digoxin, but is deteriorating, with marked cardiovascular signs.

The accompanying table summarizes these cases. It will be seen that in them all the signs of excess thyrotropic hormone are present, but that in group I the B.M.R. is consistently low; in group II it bears no constant relation to the eye condition and is extremely variable, although somewhat related to the performance of a thyroidectomy; whereas in group III it is consistently high. This would appear to bear out the contention that proptosis and ophthalmoplegia are not related to thyroxine excess.

The last column shows treatment and its effects. It is noteworthy that, in spite of Mulvany's contention that tarsor-

rhexy is useless in thyrotropic exophthalmos and that Naffziger's orbital decompression is indicated, all the cases in groups I and II have done well when treated with tarsorrhaphy and thyroid extract.

The patients in group III cannot be given thyroid extract and must be treated symptomatically, further work being necessary to decide the relative value of the various possible procedures.

CONCLUSION

It would appear that the signs of excess thyroxine include: loss of weight; rapid pulse; raised B.M.R.; soft, moist skin; lid retraction; and lid lag (von Graefe's sign), whereas those of anterior-lobe pituitary thyrotropic hormone consist of: orbital, lid, and conjunctival

TABLE 1
DATA ON 18 CASES OF EXOPHTHALMIC OPHTHALMOPLÉGIA

Groups	Case Number	Age	Sex	B.M.R.	Edema	Ophthalmoplegia	Thyroidectomy	Treatment	Result
I	1	54	F	-9	++	—	no	Thyr. Ext.	Cured
	2	54	F	-27	++	+	no	Thyr. Ext. and tarsorrhaphy	Improved
	3	57	M	-1	+++	+++	no	Thyr. Extr. and tarsorrhaphy	Cured
	4	47	F	?	++	++	yes	Tarsorrhaphy	Improved but died later with thymus tumor
II	1	44	F	+3	+	++	yes	Thyr. Ext. and tarsorrhaphy	Much improved
	2	47	M	-10	+	+	yes	Thyr. Ext.	Cured
	3	47	F	0	+++	+++	yes	Thyr. Ext. phenobarbitone and tarsorrhaphy	Much improved
	4	54	F	+58	+	+	yes (later)		Stationary
	5	56	F	+13	++	++	no	Aminophyllin and rest	Practically cured
	6	57	F	-4	++	+	yes	Thyr. Ext.	Improved
	7	60	M	+27	+	++	no	Tarsorrhaphy	Improved
	8	62	F	+2	+++	+++	yes	Thyr. Ext. and tarsorrhaphy	Practically cured
	9	71	F	+25	++	++	no	Phenobarbitone	Stationary
	10	76	F	-10	+	++	no	Thyr. Ext.	Improved
III	1	42	M	+10	++	+++	no	Tarsorrhaphy, progynon, Lugol's solution, Testosterone	Much improved
	2	53	M	+38	+++	+++	no	Tarsorrhaphy x-ray to pituitary	Much improved
	3	60	F	+32	+	+	not previous	Tarsorrhaphy and partial thyroidectomy	Cured
	4	60	M	+43	+	++	no	Tarsorrhaphy, progynon	Improved

edema and infiltration; hence—proptosis, ophthalmoplegia, fundus changes (papilledema, engorgement, macular exudate), lid edema, chemosis, eversion of conjunctiva—all of which may or may not be associated with deficiency of thyroxine. The latter will show itself as: low B.M.R., gain in weight, thick, coarse skin, and slow pulse.

Eighteen cases are described in an attempt to assess the various signs and

symptoms met with in so-called exophthalmic ophthalmoplegia.

My thanks are due to my colleagues and particularly to the following co-workers who have referred cases to me: Prof. H. Cairns, Prof. A. W. M. Ellis, Miss D. Beck, Mr. Dukes Bower, Dr. J. A. Fisher, Dr. A. Gillie, Mr. A. C. Houlton, Mr. G. Livingston, Mr. T. Negus, Dr. W. R. Playfair, and Dr. J. N. Wheeler.

BELGIAN OPHTHALMOLOGY DURING THE WAR

FELIX BONHOMME, M.D., AND HOWARD AGATSTON, M.D.

Liège, Belgium, and New York

HISTORY

PERIOD OF OCCUPATION

The Germans invaded Belgium in August, 1939. In the general mobilization of troops to guard the border one ophthalmologist was attached to each Army Corps and one to each military hospital. It was not long, however, before the Nazis dissolved the Medical Corps and either sent the doctors to Germany as prisoners or distributed them to the Belgian Red Cross and other organizations. Only a handful of ophthalmologists remained in Belgium. In Liège, Prof. L. Weekers stayed to give his services to the Red Cross, which cared for wounded civilians and for Belgian, French, and German soldiers. In Brussels, the private eye clinic of Professor Coppez was absorbed into the Belgian Red Cross under the title of Auxiliary Hospital Number 138. Ocular injuries of both military and civilian personnel were treated. These consisted largely of contusions, perforations, and intraocular foreign bodies. Many were transferred to the Louvain University Hospital of St. Pierre, which was retained by the Belgians. The Brugmann Hospital in Brussels was taken over by the Germans. The Nazis attempted to dominate the Universities of Louvain and Brussels, but the Belgians resented their control to such an extent that all normal activity was virtually paralyzed. Despite these unfavorable conditions, efforts were made to continue teaching clandestinely, and, under the direction of Professor Coppez, ophthalmology was taught to scattered groups of students.

Although a small number of doctors coöperated and even collaborated with the enemy, as a group they conducted them-

selves in a praiseworthy manner. Doctors, nurses, and medical technicians were well represented in the underground movements. Scientific research was carried on despite rather discouraging conditions. After 1939, the Belgians no longer received British and American scientific journals, although French publications were allowed entry. The Swiss continued to publish "Ophthalmologica," but the journal failed to arrive. The *Acta Ophthalmologica* of the Scandinavian countries continued to appear regularly as did all the German periodicals. Because of the war, the articles were of a practical nature; that is, on the subjects of war surgery, intraocular foreign bodies, physiology, and special visual examinations for aviators. They also dealt with the development of substitute medications due to a lack of atropine, homatropine, pilocarpine, and eserine. Belgian physicians continued to write, and their articles appeared in Swiss and Scandinavian reviews and in their national periodicals. Publication of the *Bulletin of the Belgian Academy of Medicine* was prohibited after the first two years of the German Occupation. In Louvain, clinical and laboratory research was handicapped by the burning of 800,000 volumes. The lack of chemicals—for example, alcohol, benzine, xylol, and balsam—glassware, and specialized apparatus was a big handicap. Experimental animals were obtainable only at exorbitant prices, and it was virtually impossible to feed them without dealing in the black market. A study of the use of heparin in treatment of thrombosis of the retinal veins was interrupted because the drug could no longer be obtained. Despite all these drawbacks, a

number of research problems were successfully completed and the more important of these will be discussed.

PERIOD OF LIBERATION

The bombings, violent ground combat, and flying bombs which preceded and followed the Liberation (September, 1944) brought about a procession of the gravely wounded. Splinters of glass projected with violence by the explosions caused serious traumas to the eyes and faces of civilian victims. For example, there was the explosion of a train loaded with ammunition in the station of Marloie, a small village in the Ardennes. Following this catastrophe, 17 enucleations had to be performed because of grave ocular perforations. At the time of the liberation of Liège, the Germans sent three tanks loaded with dynamite into densely populated places, causing a great number of killed and wounded. There were about 30 people with severe eye injuries, the majority of which were caused by glass splinters.

Before the war, it was through the Belgian-American Education Foundation that the Belgians had learned much of American medicine. During the last year of the war a number of U. S. Army hospitals were set up in Belgium, and this gave the doctors of both countries a new point of contact for the interchange of literature and clinical experiences.

INFLUENCE OF THE WAR ON OCULAR DISEASES

DIET

Belgium is an overpopulated industrial country. Her population of 8,250,000 inhabitants, in an area of only 11,750 square miles, is the most crowded in Europe.

Obviously, such a country could not supply its food requirements from home produce. The deficit was made good by

imports from overseas, estimated to represent 70 percent of the calories contained in the normal Belgian diet. A scarcity of food was therefore inevitable within a few months of the German arrival. Instead of the 1,500 calories that every Belgian could receive from the food produced in the country, a theoretical official ration provided for only 1,200 calories in 1940, and 1,160 calories in 1942. And even these amounts were not obtained because the quantity of rations actually distributed was always less than the quantity officially prescribed. The rations distributed provided only 900 to 1,000 of the 2,400 calories required by an adult person.

The table on page 676 compares the basic foods available in Belgium before the war and at present. It should be noted that the values given refer only to articles of prime necessity, the only ones with which the great majority of Belgians can now be concerned, although before the war they consumed in addition a quantity of accessory products of high nutritive value.

The food scarcity shown by this table is attributed to Nazi pillage.

The figures given show that the food supply of the average Belgian was dangerously inadequate. It could only lead the adult to an early grave and permanently impair the health of children and adolescents.

Govaertz, Brull, and Dumont¹ studied the nutritional state and nitrogen balance of the adult population at the outset of the war. The 1,300- to 1,500-calorie diet resulted in an average weight loss of 12 percent among the clinic patients at Liège University. Even in those who were not thin, the plasma proteins dropped 10 to 20 percent and sometimes 50 percent. The protein deficit, made particularly acute by a low-calorie diet, is the basis for nutritional edema.

TABLE 1
COMPARATIVE TABLE OF BASIC FOODS

	Average daily consumption before the war	Country's productive capacity	Amount issued during the war
Bread	430 grams (15 oz.)	325 grams (11 oz.)	225 grams (8 oz.)
Potatoes	560 grams (1¼ lbs.)	1100 grams (2½ lbs.)	150 grams (5 oz.)
Meat	110 grams (Nearly 4 oz.)	98 grams (3. oz.)	24 grams (under 1 oz.)
Sugar	77 grams (2⅔ oz.)	100 grams (3½ oz.)	48 grams (1¼ oz.)
Butter & Fats	58 grams (2 oz.)	30 grams (1 oz.)	10 grams (⅓ oz.)
Starchy foods	8.3 grams (29/100 oz.)	6 grams (21/100 oz.)	1.65 grams (6/100 oz.)

OCULAR TUBERCULOSIS

Of all the maladies for which under-nourishment is a predisposing cause, tuberculosis is the most widespread. The rise in the incidence of this disease in Belgium has been alarming. After the first winter of Nazi domination, the urban antitubercular medical centers reported a 30-percent increase in incidence. The mortality rate doubled after the first winter and trebled by the end of the second winter.

Ocular manifestations of tuberculosis were correspondingly more frequent. Iritis and iridocyclitis are particularly important because they occurred most commonly. Scleritis, sclerokeratitis, chorioiditis, retinal periphlebitis, and phlyctenular keratoconjunctivitis were also on the increase.

L. Weekers² pointed out that with rare exception ocular tuberculosis is endogenous in origin; it is secondary to an active or healed pulmonary focus. As in surgical tuberculosis, ocular cases are infrequent in advanced phthisis. Wegner³ reported three cases of ocular tuberculosis without general manifestations, and

was able to prove the etiology only at section. One of the cases he cites is the following: A woman, aged 27 years, developed bilateral iridocyclitis with retinal involvement in one eye. The local signs were those of tuberculosis, but there were no other clinical findings in support of this etiology. Her general health was at first unimpaired, later she developed a low-grade fever. She was kept under observation and treatment for several months. Her local and general condition grew worse, and the etiology remained unproved. The internist did not believe that she had tuberculosis. She died in uremia. Autopsy revealed caseous and calcareous lesions in the tracheobronchial lymph nodes. The mesenteric nodes also showed advanced caseation necrosis. Tubercles were present in the liver, and amyloid degeneration was found in the kidneys.

Schmidt⁴ reported two cases of retinal periphlebitis due to the tubercle bacillus. Here again the patients were observed for several months, but the diagnosis of tuberculosis could not be proved clinically. Necropsy alone disclosed advanced tuberculosis of the lymphatic system.

Fanielle⁵ reports encouraging results in the treatment of these forms of tuberculosis with massive doses of vitamin D (15 mg. given over an 8-day period) and calcium glycono-phosphate (5 to 20 gm. daily).

NUTRITIONAL EDEMA

During the winters of 1940, 1941, and 1942 there were a number of patients with generalized edema. They were undernourished and their diets were particularly low in protein. The syndrome was termed edema of carence.

R. Weekers⁶ studied the ocular symptoms in 15 patients who had this type of edema. Unlike the cases of Birch-Hirschfeld, they did not have hemeralopia. Despite a reduction in plasma proteins and a lowering of the albumen-globulin ratio the intraocular pressure was normal or, more often, low. These observations run contrary to the theory which states that the aqueous humour is a simple dialysate, the formation of which is regulated by the laws of osmosis.

HEMERALOPIA

In recent years, considerable work has been done on the appearance of night blindness due to undernutrition, notably inadequate intake of vitamin A. This concept is not universally accepted. Clemens⁷⁻¹⁰ and his co-workers compared dark-adaptation curves with the storage of vitamins A, B, and C in the body. The subjects were first exposed to bright light for 10 minutes, and then curves were plotted for 38 minutes or until they reached the plateau of maximum dark adaptation.

Clemens used the photoadaptometer with Birch-Hirschfeld filters.* Vitamin-

A dosage was measured by its effect on the blood serum by the method of Von Eekelen and Emmerie, using the reaction of Carr and Price. Patients complaining of night blindness, asthenopia, and glare showed curves that were at the lower limit of normal. In cases with normal vitamin-A blood levels, deficient diet was not considered the cause of the asthenopia. Owing to the variable readings in the same subjects and in different normal subjects, the normal adaptation curve was necessarily a wide band (No. 3-5 Birch-Hirschfeld filters) with upper and lower limits. Recovery rate, either at the beginning or end of adaptation, is not proportional to vitamin-A blood level. However, those with high levels did show a sharper rise. After giving 150,000 U.S.P. units of vitamin A daily for two weeks, the curves remained unchanged. In group studies the curves of 50 students taken at the end of the winter of 1942 were comparable to those of 50 others taken in the spring of 1941. The mean vitamin-A level was 8.5 gamma/10 c.c., and 7.9 gamma/10 c.c., respectively. During the war period 1941 to 1943 Clemens did not discover any case of hemeralopia due to undernutrition. He concluded that dark adaptation was a poor test for hypovitaminemia A.

There is no correlation between vitamin-B saturation in the urine and speed of dark adaptation. Similarly, no relationship exists between the degree of adaptation in any part of the curve and the level of vitamin C in the blood. In subjects whose blood vitamin C was definitely low (less than 2.0 mg.) dark adaptation remained normal.†

* Time is recorded on the abscissa of the graph and on the ordinate the numbers of the graded filters are placed. According to Zaffke, filter No. 12 corresponds to 13 millilux, and filter No. 19 to 0.1 millilux.

† The level of vitamin C was determined by the method of Emmeraux and Van Eekelen and varied from 0.97 to 16.5 mg. per liter. The average was 3.7 mg.

KERATOCONJUNCTIVITIS

Coppez¹¹ observed an increase of one type of this disease during the war. It begins with a severe conjunctivitis and secondarily involves the anterior portion of the cornea, where it produces characteristic round lesions. Since it appears epidemically in the same season as upper-respiratory infections, this form of keratitis is probably due to a virus. The disease is rare in children. Binocular involvement is uncommon. Mechanical or chemical irritation acts as a predisposing cause. The treatment is conservative, and if the conjunctivitis is treated effectively, long and severe corneal complications are avoided. Although the prognosis is good and there is no systemic involvement, patients are incapacitated for one or two weeks.

OPTIC NEURITIS DUE TO NICOTINE

In all parts of Belgium, a striking increase in this disease was noted. L. Weekers and P. Joiris¹² at the University of Liège stated that the proportion of these cases compared to the total number of ocular affections was 0.07 percent before the war and in 1942, 0.33 percent. This fact helps to clarify the pathogenesis of the disease. Alcohol is excluded as a cause because it was almost unobtainable, even at exorbitant prices. In contrast, tobacco was available in quantity. The action of the tobacco toxin is considerably enhanced by undernutrition. Only the aged were affected, the average being 59 years, and without exception all were considerably underweight (average 11 kg.). Weekers and Joiris believe that tobacco, alcohol, and poor health are the factors which in different combinations lead to retrobulbar neuritis. Tobacco is the only one of the three which alone may cause the disease. Poor general health and chronic alcoholism either alone or together will not produce retrobulbar neuritis, but they are important predisposing

causes. General body weakness, regardless of the cause, favors the toxic action of tobacco on the optic nerve and the retina, and alcohol lowers both local and general resistance of the body. The authors suggest that this disease be called nicotinic neuritis and not tobacco-alcohol neuritis, because the tobacco toxin is the only specific cause.

PUBLICATIONS DURING THE WAR

CORNEA

Appelmans and Gathy¹³ described the lesions caused by the projections of the caterpillar against the eye. The disease is divided into two phases. In the first of these, the eyelids and bulbar conjunctiva are involved, due to the vesicant action of the venom carried in the hairs. It is characterized by subjective complaints such as diminishing vision, pain, photophobia, lacrimation, and active inflammation with pericorneal injection, corneal edema with vesicles, and superficial ulcerations. This acute reaction subsides as the action of the toxin diminishes. The second phase is a chronic process resulting from the presence of hairs as foreign bodies. Photophobia and ciliary injection are absent, and the visual acuity improves. The hairs excite the formation of absorption bodies, which are identified under the slitlamp as nodular opacities in the corneal stroma.

L. Weekers and R. Weekers¹⁴ treat severe painful ulcers of the cornea by retrobulbar injection of 1 c.c. of 40-percent ethyl alcohol after anesthetizing the tissues with procaine. They also use minimal amounts of heat generated in the tissues by contact with a diathermy needle. They state that this procedure is the treatment of choice and should be tried early.

Van Lint¹⁵ treats ulcers of the cornea by retrobulbar injection of procaine in addition to the topical application of tincture of iodine.

LENS

R. Weekers¹⁶ investigated the chemistry and metabolism of the lens. Depending on the concentrations used, perhydro (hydrogen peroxide 30 percent) and sodium iodate inhibit or retard the glucose consumption of an aqueous extract of the lens. Whether this is by direct or indirect action is unknown. Sodium iodate causes opacification of a lens isolated *in vitro*. This results from the arrest of carbohydrate metabolism due to a direct toxic action of the oxidizing agent on the protein of the lens cortex.¹⁷⁻²⁰

In the course of naphthaline poisoning, carbohydrate metabolism is retarded. The slitlamp shows the first opacities of the lens before glucose consumption is increased or decreased. Therefore the arrest of glycolysis cannot be considered as a cause of cataract.²¹

In the rat, ingestion of galactose produces severe polydipsia and polyuria, with an increased output of calcium in the urine and a reduction in the blood calcium. This effect is more pronounced in the young animal than in the adult. A relationship exists between the appearance of the hypocalcemia and the opacification of the lens. However, hypocalcemia is probably only one of the factors in the formation of cataract due to ingestion of galactose.²²⁻²⁵

In diabetic patients it is somewhat common to see moderate transitory hypermetropia following a reduction of carbohydrate in the diet or following insulin treatment. This hypermetropia is due to lens changes.²⁶

R. Weekers²⁷ studied nine cases of cataract due to hypocalcemia. Seven of these followed thyroidectomy with parathyroidectomy, and two resulted from idiopathic tetany. By elevating the blood calcium to a normal level with vitamin D and calcium salts, the author was able in

favorable cases to prevent the formation of cataract and even to bring about a recession of beginning cataractous changes.

François²⁸ studied the influence of immunologic factors on the production of congenital lens opacities. The injection of lens protein in animals produces specific precipitins which can be differentiated from other animal proteins. There are two types of soluble protein in the lens, A and B. They are immunologically different and are organ but not specie specific. Fraction A is immunologically active in the homologous animal.

The total lens protein and the B fraction do not produce antibodies when injected into a homologous animal but do when injected into a heterologous animal. On the contrary, fraction A produces specific precipitins in both instances. François in his first series of experiments injected rabbits with lens emulsion and confirmed the antigenic properties of lens proteins and their specific character. The liberation of lens fragments by discission, however, does not produce an appreciable concentration of precipitins and the animal is incapable of hypersensitization to its own lens protein. The author was unable to demonstrate antilens precipitins in patients with cataracts either before or after cataract extraction. The intradermal reaction to lens protein in normal individuals and in patients with cataracts before and after operation shows evidence in certain cases of skin hypersensitivity, but is not of diagnostic or prognostic value.

In another series of experiments the author produced congenital cataract immunologically. To obtain this effect he injected pregnant rabbits with lens emulsion. About half of the litter had lens opacities. If the injections were done six weeks before conception rather than during pregnancy, 64 percent of the young showed lens opacities. These opacities

were bilateral and did not change during the subsequent development of the animal. They were often so small that it was possible to see them only under a biomicroscope. From this series of interesting experiments, the author concluded that these congenital cataracts must be due to an immunologic phenomenon in which the appearance of cataract is due to the fact that during fetal life the vascular capsule of the lens permits antibodies to enter into direct contact with lens antigen but after birth the lens is impermeable to antibodies.

L. Weekers²⁹ describes a technique for fenestration of the posterior lens capsule in cataract extraction. It consists in tearing the posterior capsule of the lens with a minute iris hook after extracapsular extraction of the cataract. The procedure is considered safer than intracapsular extraction, and the functional results are excellent.

UVEA

Harada's disease³⁰ is rare in Europe, but in the Far East, especially in Japan, it is endemic. The authors made a table of all the characteristic symptoms as follows: (1) Ocular signs consisting of bilateral uveitis with retinal detachment. (2) Neurologic signs consisting of increased intracranial pressure with lymphocytes in the spinal fluid, vertigo, insomnia, and loss of hearing. (3) Changes in the pilous system, graying of the hair, baldness, and sometimes vitiligo. It behaves like an infectious disease due to a special uveo-neurotropic virus related to that of sympathetic ophthalmia. Pirot and Heintz related observations they made on two cases, the first ones to be reported in Belgium. These patients presented classical symptoms, but the course of the disease was accelerated and resulted in rapid loss of vision. In the first case, the onset was sudden, with frontal headaches of

such intensity that repeated lumbar punctures were necessary for relief. The uveitis was total and so severe that it resulted in complete loss of vision and atrophy of the globe. The second case was slow in onset, and the inflammatory process resolved after eight months, but two serious complications occurred bilaterally; namely, glaucoma secondary to seclusion of the pupil, and cataract. No specific therapy is known.

RETINA

Röskam, Kilgus, and Bonhomme³¹ reported a case of cerebral and retinal thrombosis treated with heparin. This drug prolongs bleeding time considerably and so its use in cases of bleeding from important vessels—that is, cerebral hemorrhage—is contraindicated. Before heparin is given the diagnosis of cerebral thrombosis must be firmly established. This is sometimes possible, as in the present case, by finding coincident thrombosis of the retinal veins. The authors believe that the heparin treatment is effective in cerebral and retinal thrombosis, and they anticipate its use in thrombosis elsewhere; for example, in the heart. Heparin was injected intravenously in the following doses: 150 mg. twice a day for the first 3 days; 100 mg. twice a day for the next 19 days; 75 mg. twice a day for the next 20 days.

Appelmans³² describes the various causes of retinal hemorrhage. He stresses essential hypertension and states that simple retinal hemorrhage does not have the grave prognosis of the angiospastic retinopathy of Volhard, in which 85 percent of the patients affected die within two years following the appearance of hemorrhage.

Coppez³³ was the first to discover the use of the pyrometric electrode in the treatment of retinal detachment. This electrode permits the exact measurement of

the temperature of the tissues at the point of application. At any moment it may be read on the dial of the pyrometer. The reactions obtained correspond identically with the reading. The electrode is based on the thermocouple principle, being a combination of a surface electrode and a thermometer. Coppez has shown that the surface area of the electrode, the duration of application, and the temperature are essential factors in the ultimate result. Optimum conditions are a surface 2.5 mm. in diameter, and 20 seconds of application at a temperature of 80°C. Operative technique: Coppez withdraws the active electrode from a tube of trioxymethylene and then applies it flatly on a well-dried and denuded scleral surface at the level of the tear. He checks the site of the first coagulation area in relation to the tear. It appears as a white spot with blurred margins. The tear is then sealed off and obliterated by a number of coagulations. The subretinal fluid is then evacuated by means of several perforations made at the level of the surface coagulation with a 1.5-mm. electrode. Sixty percent of all the cases and 80 percent of all those considered favorable were cured by this method. Coppez concludes his paper with a discussion of pathogenicity and states that detachment of the retina is secondary to a vascular lesion.

ANGIOSCOTOMETRY

After reviewing the work of John Evans, Weekers and co-workers³⁷ studied the subject rather intensively. They devised a technique for recording physiologic angioscotomas on the Bjerrum screen placed at a distance of one meter from the eye. They describe their method in detail.

Following a study of a comparison of the retinal vessels in fundus photographs with angioscotomas, they reached the following conclusions:

1. The recording of physiologic angioscotomas is easier and more exact when the lighting for the screen is less than 3 lux.

2. The optimum speed of movement of the test object is one degree every two seconds.

3. The optimum diameter of the test object varies with the degree of lighting for the screen and the caliber of the vessels studied.

4. The size of an angioscotoma is a little larger than a projection of a photograph of the corresponding retinal vessel on a visual-field chart.

5. The density of the angioscotomas is greatest centrally and decreases towards the periphery.

6. In favorable cases it is possible to distinguish arterial from venous angioscotomas.

7. The origin of pathologic angioscotomas appearing in the course of ocular or general disease remains hypothetical and requires further study.

Weekers³⁹⁻⁴⁰ found angioscotometric changes in cases of posttraumatic cerebral syndrome; namely, pathologic enlargement of the scotomas and an increase in their density. There is often a corresponding reduction in visual acuity and retinal asthenopia. These scotometric abnormalities probably result from a change in the conduction of impulses through the retinal neurons and synapses, which, in turn, seems to be due to disturbed circulation in the central retinal vessels.

GLAUCOMA

According to R. Weekers⁴¹ chronic simple glaucoma is accompanied by vascular lesions in the uvea, retina, and optic nerve. They give rise to the three cardinal symptoms of the disease; namely, ocular hypertension, visual-field defects, and excavation of the optic papilla. These three signs usually coexist, but in some

cases the hypertension is absent. One may then ask, should patients with optic-nerve atrophy, excavation of disc, and atypical visual-field changes be designated glaucomatous? Weekers,⁴² in another publication, describes a disease consisting solely in pallor of the disc with typical glaucomatous excavation but without any other anatomic changes. Retinal function is intact. The disease is acquired and is observed in middle and older-age groups, particularly in patients with advanced arteriosclerosis. The progress of the disease is very slow. In time, defects in the visual field and ocular hypertension may supervene. This suggests that the original optic-nerve lesion is related to glaucoma.

L. Weekers and R. Weekers⁴³ made a histologic and biomicroscopic study of two human eyes and the eyes of several cats on which microcoagulation of the ciliary body was performed. The authors conclude that all surgical operations for relief of glaucoma are by their very nature traumatic. All produce a change in the intraocular vascular circulation and a new equilibrium between aqueous and blood of varying duration. Intraocular pressure is decreased. Surgery is specific in that it affects the anterior uvea, the seat of formation of the aqueous. Diathermy of the ciliary body produces maximum damage to the aqueous-forming structures with minimum trauma and without opening the globe, thereby lessening the danger of postoperative infection.

All operations for chronic glaucoma create persistent vasodilatation in the uvea, especially in the ciliary body. This results in increased absorption of aqueous humor. As a late effect, a variable degree of atrophy of the ciliary body occurs and contributes to the hypotensive effect by decreasing production of the aqueous. L. Weekers and R. Weekers say that the cyclodiathermy operation without penetration or perforation of the sclera ac-

complishes this effect. The operation is indicated in secondary and absolute glaucoma. Coppez also describes an operation for glaucoma in which he uses diathermocoagulation with his pyrometric electrode. This is a modification of Vogt's technique.

MISCELLANEOUS

Coppez⁴⁴ reviewed the eye signs and symptoms in posttraumatic cerebral syndrome. Among the subjective symptoms the author emphasizes vertigo, headache, and psychical asthenopia. The functional symptoms, such as decrease in visual acuity and narrowing of the field of vision, the exact character of which is not always known, are considered less important. Great importance, however, is attached to the objective symptoms, namely:

1. The lability of the pressure in the retinal arteries and the disproportion to the brachial pressure. (These disturbances in the circulation are the expression of similar circulatory disturbances in the brain and have no relation to the cerebrospinal-fluid pressure.)
2. The retinal hypertension is characterized by the narrowing of the caliber of the vessels. Another somewhat frequent sign is the peripapillary edema, generally localized in the nasal sector of the optic disc.

Coppez⁴⁵ reported a case of bilateral hysterical blindness cured by convulsotherapy. The healing mechanism is not to be explained by the feelings of fear and of death set up by the injection of pentamethylentetrazol, but by the release of the blocking of intracortical association paths as seen from the electro encephalograms, and also by the severe disturbances of the cerebral circulation as shown by the measurement of the retinal-arterial blood pressure.

Appelmans and Van den Berghe,⁴⁶ in a paper on the ocular lesions associated with pellagroid dermatosis, reported a

case in which the cutaneous manifestations of pellagra were coupled with the ocular changes of ariboflavinosis. In each of three exacerbations, the ocular and cutaneous lesions coexisted. The patient presented a marginal arcuate opacity with conjunctival injection and bilateral superficial punctate keratitis. Iritis was limited to the left eye, and there was considerable photophobia and reduction in vision. The cutaneous lesions were typical of pellagra. Since adequate dosage of nicotinic acid and riboflavin did not result in specific cure, the author concluded that this was not pellagra.

Appelmans and Lams⁴⁷ described the

macroscopic and microscopic lesions found in the eyes and optic nerves of dogs inoculated with *Trypanosoma marocanum* as follows: 1. Nonsuppurative interstitial keratitis with several foci of scleritis and episcleritis without ulceration. 2. Acute suppurative iritis followed by chronic iridocyclitis and disseminated choroiditis. The retina remained normal. 3. All of the ocular media were cloudy. The lens showed degenerative lesions which progressed to total cataract. 4. Optic neuritis and perineuritis.

OXYCEPHALY ASSOCIATED WITH KLIPPEL-FEIL SYNDROME AND OTHER SKELETAL DEFECTS

A. L. PETER, MAJ. (MC), A.U.S.

Camp Lee, Virginia

Oxycephaly is a congenital malformation of the skull of unknown etiology but probably developmental in origin which has been thoroughly studied and reported upon, especially in the various ophthalmologic and neurologic journals. Recent textbooks on neurology devote impressive amounts of space to this congenital deformity.

The following four cases are presented because they were noted in soldiers who had been recently inducted into the Service, and who had only mild or moderate changes associated with this condition. They are being reported primarily to demonstrate the fact that this condition will exist in mild forms, producing variable symptoms which may go undiscovered for extended periods of time.

Oxycephaly is of interest to the ophthalmologist because the majority of the patients exhibiting this condition present numerous ocular findings. The most common ocular symptom is that of exophthalmos. This varies from a mild degree to extreme proptosis and extrusion of the globe. Ptosis is frequently seen, as is an inability to close the lids completely. The exophthalmos probably is secondary to the very shallow orbits, so that there is insufficient room for the globe and the surrounding soft tissues.

Next in frequency in the common eye findings is strabismus. This is usually of the divergent type, although a few cases have been reported showing a convergent squint. Frequently, also, there is a weakened, or loss of, convergence.

A further eye finding is nystagmus of the ocular type. It is probably secondary to the strabismus and poor vision which exists in these conditions.

Impairment of vision is usually present to some degree. It frequently is more marked in one eye than in the other. The loss of vision is due to optic atrophy of the secondary type, although cases have been reported in which this has not always occurred. Three of the four cases presented here show mild degrees of atrophy that cannot be classified on a secondary basis.

There is a difference of opinion as to the exact cause of the atrophy. Davis¹ thought that it resulted from a narrowing of the optic foramen. Greig² believed that a malformation of the middle fossa and a consequent stretching and pulling of the optic nerve produced the changes. Increased intracranial tension, stenosis of various foramina transmitting blood vessels, and abnormalities of the internal carotid artery resulting in compression of the optic nerve have also been advanced as possible causes for the nerve palsy.

Abeles³ reported a number of cases of oxycephaly showing medullated nerve fibers, in which the pupils were widely dilated; none of my four cases, however, demonstrated this condition.

The most striking physical finding is the skull deformity, which may vary from a merely tall head to the more typical "tower skull." The skull is short in its anterior-posterior diameter; the forehead is high, with an associated widening or bulging of the temporal fossae. The orbits are usually shallow; supraciliary ridges may be absent or only faintly marked. The cheek bones are flattened, and there is frequently prognathism and a high narrow palatine arch. Occasionally marked septal deflection is present.

The X-ray findings are diagnostic, the

Fig. 1 (Peter). Klippel-Feil syndrome coalescence of cervical vertebra (case 1).

most striking feature being the appearance of the bones of the calvarium. They appear extremely thin and pitted all over with shallow depressions on their inner surfaces, said to correspond with the underlying convolutions of the brain but often more circinate and regular than these. They are known as digital impres-

sions. The vessels are exaggerated. The suture lines are obliterated. The orbits are shallow and there may be a definite protrusion of the brain as a result of an actual break of the skull. The anterior fontanels may remain widely open. The middle fossa is frequently pushed down to the level of the posterior fossa, and the anterior fossa is shortened and distorted.

Oxycephaly, as a rule, is associated with other congenital or developmental defects, and the four cases presented below are no exception. Among the various other defects present in these cases are: Brevicollis (or Klippel-Feil⁴ syndrome), patent parietal foramina, arachnodactylism, congenital deformities of toes, and other spinal-column defects.

The first case demonstrates brevicollis and also patent parietal foramina.

Brevicollis or Klippel-Feil syndrome consists of an absence of cervical vertebrae, and the following conditions are usually present. There is ordinarily a short neck and a low posterior hair line, with

Fig. 2. (Peter). Lateral view showing fusion of bodies and processes of cervical vertebrae (case 1).
Fig. 3. Patent bilateral parietal foramina and tower skull (case 1).

limitation of head movement. Roentgenograms show vertebral reduction and coalescence in the cervical spine. The X-ray observations of this syndrome have been described by Rechtman and Horwitz⁵ (figs. 1, 2).

The parietal bone, bilaterally near the upper posterior angle, normally exhibits a minute opening through which passes an emissary vein. This opening is the parietal foramen. It may be absent, or, although faintly present, may be closed. Occasionally, it is doubled. The abnormally large foramina probably result from an irregularity in the process of ossification at the closure of the related fontanel (D. Greig⁶). The first case presented below demonstrated patent bilateral parietal foramina, and Klippel-Feil syndrome (figs. 3, 4).

The remaining three cases show spinal-column defects and deformities of the fingers and toes.

CASE REPORTS

CASE 1. A colored man, aged 22 years, gave an essentially negative family history. His father had died when the patient was nine years old, and had been blind in one eye. The mother and seven

Fig. 4 (Peter). Skull showing high forehead, digital impressions, and no suture lines.

Fig. 5 (Peter). Note tower skull, short neck, low posterior hairline.

brothers and sisters were living and well, wore no glasses. The patient was the fifth and had been normally delivered. No defects in the siblings could be determined. The patient himself had had no operations nor illnesses and denied all venereal diseases. His present chief complaint was headache, swelling of the eyes, and, since entering the Service, inability to wear a helmet.

Examination. The patient was not acutely ill. **Head.** He had a definite skull deformity—dome-shaped, with decreased anterior-posterior diameter (fig. 5). The forehead was high. Palpation of the skull in the region of the parietal foramina revealed large defects bilaterally. Pulsation could be obtained on motion of the head forward and to the dependent position; no pulsation at any other point in the skull (fig. 6).

Eyes. Vision was O.U. 20/20. There was a slight bilateral ptosis. Pupillary reactions were normal. Exophthalmos was 19 mm. O.U.; tension 15 mm. Hg (Schiötz) O.U. There was exotropia

Fig. 6 (Peter). X-ray view showing tower skull.

for distance and near. Convergence near point measured 14 cm.; accommodation 9 P.D., O.U. The media were clear, the fundi negative, except for the nerve head, which was slightly pale for this race. The vessels appeared to be normal. There was no evidence of previous inflammatory reaction. Visual fields showed a moderate concentric contraction for form. The color vision was normal.

Ears. Ear canals and drums were normal. Hearing to whispered voice, 15/15 A.U. The audiogram showed a bilateral mild type of perceptive deafness. *Nose.* The septum was folded and deviated to the right. The nasal mucosa was normal; there was no discharge. *Throat.* Observed were a high narrow palate; small, cryptic tonsils with a slight amount of chronic

infection. In relation to the Klippel-Feil syndrome the folded septum and high palate are interesting. The patient gave no history of nose injury.

The neck was short, with hairline extending lower than is usually seen. There was slight limitation of motion of the head but without pain (see X-ray reports). Both hands showed lateral deviation of fifth fingers. The remainder of the physical examination was essentially negative.

X-ray studies. There was a congenital anomaly of the skull which revealed evidence of a turrecephaly, a form of craniostenosis. Two well-defined areas of radiolucency, equidistant from the sagittal plane of the skull, were situated in the posterior portion of the parietal bone, each equal in size and measuring approximately 2.5 cm. in diameter. These areas were due to the enlarged parietal foramina. The cervical spine showed almost complete fusion of the bodies of the third and fourth cervical vertebrae, as well as their posterior articular appendages. The axis was asymmetrical in appearance, and there was a protrusion extending from the lateral masses' right side, which

Fig. 7 (Peter). Lateral deviations of fifth fingers' distal portions.

formed a joint space with another portion of bone that appeared to descend from the right side of the atlas. The dorsal spine revealed a *spina bifida occulta* of the first dorsal vertebra. There was almost complete sacralization of the transverse processes of the 6th lumbar vertebra. Both hands showed congenital anomalies of the distal portions of the fifth fingers, which were deviated laterally (fig. 7).

Laboratory. All tests, including the Kahn, were negative.

CASE 2. A colored man, aged 20 years, 5 ft. 7 in. in height, weight 145 lbs.; showed a definitely high head with high forehead, symmetrical. The skull was dome-shaped or a typical tower skull (fig. 8).

His father and mother were living and well; he was the fifth of nine children (three brothers and five sisters), living and well. All members of family were of apparently normal mentality, there were no congenital deformities. The patient had finished the eighth grade. He had had no illnesses of any kind, as far as he knew; no operation, except tonsillectomy at the age 12 years; and he denied all venereal diseases.

For as long as he could remember he had had trouble with his eyes, consisting primarily of pain and swelling of eyes. He also complained of headache, but his chief difficulty since entering the Service had been inability to wear a helmet.

Examination. The eyes. Vision O.U. was 20/20. There were a bilateral, mild ptosis and exophthalmos: O.D. 19 mm.; O.S. 21 mm. Exotropia was present for distance and near. Accommodation, O.U. 7.5—8.5 PD.; Pcb., 10 cm. Pupillary reactions were normal, the pupils normal in size. The anterior segments were normal. The discs were both slightly pale, that of the left eye showing on the nasal

Fig. 8 (Peter). Showing side view of head (case 2).

side a large amount of fibrous tissue. The visual fields for form showed a moderate concentric contraction. Color vision was normal. Tension O.D. and O.S. 14 mm. Hg (Schiotz).

Ear, Nose, and Throat. The patient complained of difficulty in breathing through his nose, alternating in character for as long as he could remember. Ear drums and canals were normal. Hearing to whispered voice was 14/15 A.U. The audiogram revealed a moderate amount of bilateral nerve-type defective hearing. The septum of the nose was straight, the nasal mucosa congested, particularly on the right. There was no discharge. The palate arch was moderately high, there were malocclusion and bilateral, small tonsillar tags.

The neck, somewhat short, was otherwise negative.

Fig. 9 (Peter). Lateral view of skull, showing absent suture lines, thinning of cortex, and increased digital markings (case 2).

The thorax showed curvature of the dorsal spine, mild kyphosis, and lateral curvature, with apex to the left between the scapulas. There was asymmetry of the thoracic cage.

Blood pressure was 118/80.

The hands and feet showed lateral de-

viations of the fifth fingers, bilateral and lateral obliterations of the toes.

X-ray studies. Examination of the skull revealed obliteration of the suture lines of the frontal parietal sutures; there was some thinning of the cortex of the frontal bones; the digital markings corresponding to the convulsions of the brain were accentuated. The anterior fossa appeared slightly elevated when compared with the normal skull and there was some elevation of the vertical diameter of the skull as compared to the transverse diameter. The dorsal spine revealed a scoliosis of the upper dorsal vertebrae, with the convexity to the right (figs. 9, 10, 11).

Orthopedic consultation found a curvature of the dorsal spine, mild kyphosis, and lateral curvature with apex to the left between the scapulas. X-ray studies showed a gross deformity, apparently a narrowing and loss of substance with fusion of the 3d, 4th, and 5th dorsal vertebrae; Sharp posterior and left lateral bowing at this point. Diagnosis: Deformity of the spine, 3d, 4th and 5th dorsal vertebrae,

10

Fig. 11. Deformity of spine, dorsal vertebrae.

blood studies were essentially negative.

Laboratory reports of the urine and with fusion and angulation, congenital. Blood Kahn and Wassermann reactions were negative. No spinal-fluid examination was made.

CASE 3. A colored man, aged 26 years, was apparently not acutely ill (fig. 12). His chief complaint was impaired vision, left eye, and inability to wear a helmet. His father, living and well, had a short second toe on the left foot. The mother, dead, of a cause unknown, had had long fingers. He had one sister, living and well, and two half-brothers, well. There was no history of impaired vision or skull deformity in the immediate family. The patient had finished high school and three years of architectural drawing.

At the age of 14 years he had been struck with a ball, with injury to the left eye. Headaches were severe up to the age

Fig. 12 (Peter). Oxycephaly in case 3.

Fig. 13 (Peter). Arachnodactyly of fingers (case 3).

of 17 years, since then only rare.

Examination. Head. There was a definite skull deformity with narrowing of the anterior-posterior diameters, high forehead, and slight bulging at the temporal fossa. No pulsations were noted anywhere.

Eyes. Vision was O.D. 20/20; O.S., light projection. There was bilateral exophthalmos of 20 mm. Convergence near point was 15 cm.; the accommodation O.U. 8-10 PD. The pupils were normal in size and reactions. There was ocular nystagmus on extreme lateral gaze. Pigment was deposited on the anterior lens capsule, bilaterally; the vitreous of the right eye was negative; in the left eye there were many fine opacities, granular and pigmented. The disc of the right eye was negative; that of the left, pale, with marked fibrosis of the vessels leaving the disc, and also in periphery. In the macular area was a large, healed area of chorioretinitis, with a vertical choroidal tear, temporal to the macula. The visual field of this eye showed marked contraction for form; that of the right, moderate contraction. Tension O.U., was 21 mm. (Schiotz).

The fingers were somewhat long, tapering, and spiderlike (fig. 13). A deformity of the second toe of the left foot suggested absence of the middle phalanx

Fig. 14 (Peter). Congenital deformity of second toe, left foot (case 3).

(figs. 14, 15). The remainder of the physical examination and laboratory studies, including blood Kahn test, was essentially negative.

X-ray studies. The skull was congenitally deformed as to shape and increased in height (fig. 16). There were obliteration of the coronal suture, due to its premature

Fig. 15 (Peter). X-ray view of deformed toe (case 3).

closure, and an increase of the digital markings in the inner table of the skull. The anterior fossa was high in position; the posterior fossa, low and elongated, occupied at least one half of the base of the skull; the middle fossa was small in appearance. Both hands presented a tendency to arachnodactyly, manifested by elongated and thin phalanges, especially the distal phalanges; both feet had a hallux-valgus deformity. The middle and dis-

Fig. 16 (Peter). Absent suture lines, increased digital markings (case 3).

tal phalanges of the left second toe were small in size. The lateral view of the right foot revealed a narrowing of the antero-posterior diameter of the proximal portion of the phalanx of the third toe. These were congenital deformities.

CASE 4. The fourth case was not completely studied owing to the fact that the individual left our jurisdiction before the work-up could be completed. His chief complaint was headache, difficulty in wearing a helmet, and poor vision. The family history was not obtainable. The head showed a definite deformity, with a high forehead and narrow antero-posterior diameter, a typical tower shape.

Eyes. Vision was O.D. and O.S. 20/30, corrected to O.U. 20/20. There were bilateral and equal exophthalmos; remote

Pcb.; exotropia for distance and near; no nystagmus. The media and fundi were essentially negative. Visual fields for form showed a slight contraction.

X-ray studies. There was a congenital anomaly of the skull with an increase in the vertical diameter. None of the suture lines were visible. The middle cranial fossa was short and shallow. The sella turcica appeared normal (figs. 17, 18).

Fig. 17 (Peter). High anterior fossa, low posterior fossa, with elongation of same (case 4).

There was a spina bifida occulta of the upper sacral segment.

Laboratory tests. The Kahn reaction was positive. It was impossible to recheck it or to get any definite history of venereal disease.

CONCLUSIONS

Four cases of mild oxycephaly have been presented, showing, besides the skull deformity, other skeletal defects. The cases are presented primarily to show that this condition exists in mild form and will frequently present few, if any, symptoms.

Fig. 18 (Peter). Typical tower skull, increased digital markings, absent suture lines (case 4).

In the Service the complaint common to all four cases has been that of inability to wear the ordinary type of helmet.

One of the cases presented the unusual syndrome of brevicollis or Klippel-Feil syndrome. Other associated defects were patent parietal foramina, arachnodactylism, and unclassified deformities of fingers, toes, and spine.

A thorough fundus study on all four cases with widely dilated pupils failed to reveal any case of secondary optic atrophy (not traumatic), or the presence of any medullated nerve fibers, as reported by Abeles.

PENICILLIN IN GONOCOCCIC CONJUNCTIVITIS: ITS USE IN 30 CASES, COMPARED WITH THE SULFONAMIDES IN 173 CASES*

PHILIP MERIWETHER LEWIS, M.D.
Memphis, Tennessee

In 1941, I presented before the American Ophthalmological Society a paper¹ comparing the results of sulfanilamide, sulfapyridine, and sulfathiazole therapy in 120 cases of gonococcic conjunctivitis. Since that time an additional 83 cases have been treated, 23 with sulfathiazole, 30 with sulfadiazine, and 30 with penicillin. The marked superiority of the sulfonamides over presulfanilamide therapy

of penicillin in the treatment of gonococcic infections is also well known. In this series of cases penicillin was used intramuscularly and in many cases it was also used locally. The local use was based on the work of Struble and Bellows,³ who found that the topical application of penicillin resulted in a much greater concentration than could be secured by intravenous or intramuscular administra-

tion. As large series of gonococcic infections of the eyes have become rare, it was felt that a paper summarizing my experience with penicillin and the sulfonamides, and comparing their efficiency might prove of interest and value.

This paper is a brief résumé of the re-

sults obtained in the Isolation Hospital in Memphis with sulfonamide therapy and recently with penicillin. Our first patient with gonococcic ophthalmia treated with one of the sulfonamides was seen in June, 1937. Thereafter all patients were treated with these drugs until July, 1944, when penicillin therapy was started. In the past eight years, to this date, November, 1945, a total of 203 cases have been

Until April, 1940, sulfanilamide was used in all cases; from April, 1940, to February, 1941, sulfapyridine was used; and from February, 1941, to June, 1942, sulfathiazole. Sulfadiazine was used from June, 1942, to July, 1944. Since July, 1944, penicillin has been used routinely except in two or three cases in which it was not available. In a few severe cases a sulfonamide was used in addition to

treated. Ninety cases were treated with sulfanilamide, 22 with sulfapyridine, 31 with sulfathiazole, 30 with sulfadiazine, and 30 with penicillin. In six cases both penicillin and a sulfonamide were used. Only cases definitely gonococcic bacteriologically and clinically are included in this report. Numerous cases of conjunctivitis of supposedly gonococcic origin proved to be due to other bacteria, or to be inclusion-body blennorrhea and were therefore excluded from this series.

penicillin. In a large percentage of the cases treated in the past four years specific local treatment was also given. In the majority of cases this consisted in a solution of sodium sulfathiazole, varying from a 1- to 5-percent solution, dropped into the eyes every two or three hours. A 2.5- or 3-percent solution was found to be apparently as effective and not so irritating as the 5-percent solution. Recently penicillin in normal saline, 500 to 2,500 units per cubic centimeter has

been employed by dropping it into the conjunctival sac every two or three hours. We have not tried penicillin ointment, as recommended by Bellows,⁴ in gonococcic infections.

TREATMENT

The present routine at the Isolation Hospital is as follows: When the patient is admitted, smears are taken for examination, and if the patient has the clinical appearance of having a gonococcic infection, treatment with penicillin is started at once. For adults, 20,000 units in 2 c.c. of saline are given intramuscularly and repeated every three hours. For children, 10,000-unit doses are adequate and in infants, 5,000 units or less are sufficient in most cases. The average adult received a total of 400,000 to 500,000 units, while newborn infants usually required about 100,000 units to effect a cure.

None of our patients showed any toxic or allergic reactions to penicillin. In very severe cases, particularly those with corneal involvement, a sulfonamide in addition to penicillin is used. Sulfadiazine, being as effective as sulfathiazole, and slightly better tolerated, is employed. Sulfapyridine, although the most effective sulfonamide, is too toxic and therefore no longer used. The average adult received an initial dose of 30 to 60 grains (2 to 4 gm.) and 15 gr. (1 gm.) every four hours. In the newborn the initial dose of sulfadiazine is 0.5 gr. (.033 gm.) per pound of body weight, after which 1 gr. (.066 gm. per pound of body weight) every 24 hours, is divided and given at four-hour intervals. It is believed at present that the combined use of penicillin and sulfadiazine is very effective, but not necessary as a general routine. There seems to be no contraindication to administering the drugs simultaneously.

Besides the systemic use of penicillin and occasionally sulfadiazine in addition,

the following local treatment is used and recommended:

Mechanical cleansing of the conjunctival sac every two hours by irrigating with cool boric-acid solution, as long as gross pus is visible.

Instillation of penicillin drops, 1,000 to 2,500 units per cubic centimeter of normal saline (after irrigations) every two hours.

Iced compresses in cases in which there is considerable edema of the eyelids and conjunctiva.

Discontinuance of this treatment as soon as the eye is clean clinically and the smears are negative. This occurs usually in from 24 to 72 hours. Following this, zinc sulfate, 2 gr. (.13 gm.) per ounce (30 c.c.) is instilled three or four times a day and continued for about one week after the patient leaves the hospital.

Atropine is used only if there is corneal involvement. For more than five years it has been unnecessary to apply silver-nitrate solution to the conjunctiva, perform an external canthotomy, or give an injection of foreign protein.

RESULTS

It has been previously pointed out¹ that the success of any method of treatment of gonococcic ophthalmitis should be judged by two standards: 1. The preservation of vision, which means the prevention of ulcers of the cornea, or the healing of ulceration which may have already occurred. 2. The rapidity and ease with which a cure is obtained.

The first standard is obviously essential, but the second is of great importance, both from the standpoint of shortening the period of disability and from that of great economic saving. A review of the charts of 50 consecutive patients treated prior to the use of sulfonamides showed the average period of hospitalization to

be 20.3 days. The entire attention of one or more special nurses was not uncommon. By inspection of table 3 the great superiority and the economic saving obtained by modern therapy are obvious. The average period in the hospital was reduced by sulfanilamide to 8.9 days. With sulfathiazole the time was 6.2 days and with sulfadiazine 5.7 days. The

administration in our series of cases. There have been no failures with penicillin and no recurrences in this series.

For the past 4½ years local treatment by instillation of sodium sulfathiazole, 1 to 5 percent, or penicillin 500 to 2,500 Oxford units per cubic centimeter has been used in addition to the systemic treatment in almost all cases.

TABLE 3
COMPARISON OF RESULTS IN 253 CASES OF
GONOCOCCIC CONJUNCTIVITIS

Treatment	Number of Cases	Average Number of Days for Cure	Average Number of Days in Hospital	Unsatisfactory Results*
Presulfonamide therapy	50	17.30	20.30	18
Sulfanilamide	90	5.40	8.90	8
Sulfapyridine	22	2.57	4.85	0
Sulfathiazole	31	4.00	6.2	2
Sulfadiazine	30	3.7	5.7	1
Penicillin	30	3.0	4.6	0

* Visual damage from corneal ulceration, relapses, and very slow clinical and bacteriologic cures are placed under this heading.

period of hospitalization with penicillin averaged only 4.6 days. The average length of time for apparent cure (no pus nor edema and negative smears) with sulfadiazine was 3.7 days. With penicillin it was three days. It is interesting to note that the incidence of gonococcic eye infections has greatly decreased in recent years due to the rapidity and ease with which gonorrhea is cured by the sulfonamides and by penicillin.

SUMMARY AND CONCLUSIONS

During the past eight years and four months, 203 cases of gonococcic conjunctivitis have been treated at the Isolation Hospital in Memphis. One hundred and seventy-three were treated with sulfonamides and 30 with penicillin. Six of the patients who were treated with penicillin were also given sulfadiazine.

No toxic, allergic, nor other untoward reactions have occurred from penicillin

Both the sulfonamides and penicillin are amazingly effective in the treatment of gonococcic infections of the eye. Sulfadiazine, being quite effective and very well tolerated, is at present the sulfonamide that is recommended if penicillin is not available. Penicillin is even more effective. In infants it is easier to administer than a sulfonamide and it may be given without fear of toxic reaction.

The systemic use of both penicillin and sulfadiazine is recommended in very severe cases, especially those with corneal involvement.

To date, we have not felt it justifiable to withhold systemic therapy and rely entirely upon the local use of penicillin in gonococcic ophthalmitis, although we feel that its local use is a helpful agent and should be employed. Penicillin is at present the most effective and the most satisfactory agent for the cure of gonococcic infections of the eye.

Thanks are hereby expressed to Gilbert Levy, M.D., director of the Isolation Hospital Department of the John Gaston

Hospital, and to the hospital staff for their aid in this work.

OCULOGLANDULAR TULAREMIA*

REPORT OF THREE CASES WITH UNUSUAL CONTACTS

ARTHUR ALFRED SINISCAL, M.D.

Rolla, Missouri

INTRODUCTION

Since the occurrence of oculoglandular tularemia is becoming more common, a report of three cases which came to the author's attention within one year should prove interesting and instructive.

The oculoglandular symptom complex is not rare. An experienced ophthalmologist should encounter several cases in practice. With the knowledge that tularemia may occur anywhere in the United States, and in many foreign countries, physicians everywhere are becoming mindful of tularemia. The oculoglandular form should, therefore, be more readily recognized, and the number of cases correctly diagnosed should increase.

Within the oculoglandular-symptom-complex group may be listed the following infections: Parinaud's conjunctivitis, leptothrix conjunctivitis (sporotrichosis or leptotrichosis), tuberculous and syphilitic conjunctivitis, the so-called epidemic conjunctivitis (keratoconjunctivitis), conjunctivitis due to Pascheff's or-

ganism (*Micrococcus polymorphicus necroticans*), conjunctivitis due to *B. pseudotuberculosis rodentum*, and tularemic conjunctivitis (*Bacterium tularense*, known also as *Pasteurella tularen. is*). The last named is the most severe type, causing not only grave primary ocular symptoms, but also severe systemic (toxemic) reactions. The other types show, as a rule, manifestations limited to the head and neck, with little, if any, constitutional involvement. Oculoglandular tularemia causes a general systemic response, with malaise, chills, fever, marked prostration, and various complications; in very severe instances, it may lead to death. In all cases, the ipsilateral regional lymph nodes of the head and neck become enlarged, and occasionally also those of the axillary region, leading in severe cases to suppurative adenitis.

Local symptoms. The primary nidus of infection is in the conjunctiva, most commonly in the lower cul-de-sac. The cause of the disease is *B. tularense*. The infection is usually the result of the patient's having inadvertently rubbed or wiped the eye with contaminated fingers. The primary focus may remain limited,

* From the Missouri Trachoma Hospital Division of the Missouri State Board of Health. Read before the Saint Louis Ophthalmic Society, October 26, 1945.

or spread to other parts of the conjunctiva; it may or may not involve the bulbar conjunctiva.

The lesion begins as a reddened, yellowish papule which soon develops into a granulomatous ulcer, lying in a bed of chemotic conjunctiva. The ophthalmia is almost always unilateral, although a bilateral involvement has been reported.^{1, 2} There is little or no initial pain or tenderness. Several days after infection the lids become swollen, a condition that persists, accompanied by itching. At this time, the preauricular lymph gland may enlarge and with continued swelling may become painful and tender.

Upon everting the lids, one sees the conjunctiva to be deeply injected and chemotic, especially in the area surrounding the lesion. The latter may be single or multiple, in the latter case the ulcers may be discretely placed or scattered. The yellowish necrotic tissue that fills in the crater of the ulcer eventually sloughs off and leaves an open, rough area, indurated and thickened with granulation tissue, with raised and irregular edges. Whether single or multiple, these yellowish ulcers mark the site of entry of *B. tularensis*, and form a characteristic sign of the disease. Lying in the bed of engorged and reddened conjunctiva, they have been compared by one observer³ to yellow polka dots on a scarlet dress. There is a scant, mucoserous discharge which tends to agglutinate the lashes during sleep. As a rule, the cornea remains clear throughout the course of the affection. However, ulceration, with perforation followed by prolapse of the iris, has been reported.^{1, 2} The iris maintains its normal luster, with the pupillary reactions intact. The infection seems to limit itself entirely to the mucosa without involving the intraocular structures. Very rarely, purulent dacryocystitis may occur. Intense edema may close the lids tightly.

The general toxemia does not become severe until a week to 10 days following the initial infection, and in the interim the patient thinks of his condition as a purely local affection. Following the ocular distress, the preauricular lymph gland becomes enlarged and painful. This is distinctly palpable as a lumpy swelling immediately anterior to the tragus on the same side as the affected eye. The submaxillary glands usually become enlarged and tender; within a few days the cervical nodes also become enlarged and painful, those of the anterior triangle of the neck being the ones affected. As the disease progresses, the adenopathy becomes more generalized, so that even those of the axillary region are involved. All these nodes increase in size, and occasionally a suppurative adenitis may follow.

General symptoms. The systemic reaction usually makes its appearance within a week of the initial infection. It is characterized by malaise, recurrent chills and fever, and marked debility. Headache, backache, nausea, and dizziness are accompanying signs. The patient seeks to remain at rest. The initial fever is not high, hovering about the 100° F. level, but later rises to 102° or 103°, or even higher. During the latter period, the patient begins to experience more frequent chills and sweats, greater weakness and prostration, and mental depression. Nausea and vomiting not infrequently occur. It is at this stage that the ocular symptoms and adenopathy are most marked.

These severe toxic manifestations may last 24 hours or longer, and then subside suddenly, leaving the patient free of acute distress for several days. The respite may be of short duration, then symptoms return with the same or increased vigor. The active stage of the disease during which remissions and recurrences follow

one another may last from 6 to 12 weeks, or even longer. As the terminal stage of the infection is approached, the recurrences become less and less severe, and more infrequent.

Convalescence is long drawn out; its prolongation being one of the characteristic features of this disease. Complete recovery usually occurs from two to six months following initial infection. Upon attempting an early return to normal duties, the patient soon finds that he is unable to do the amount of work previously accomplished; weakness and readily induced fatigue occur upon the slightest exertion. In fact, this will continue even for many weeks after the force of the infection has apparently been spent, and may last for a year.

The general symptoms described are equally characteristic of the other forms of tularemia; namely, ulceroglandular, glandular, and typhoidal. However, in the oculoglandular form the general symptoms are secondary to the primary ophthalmia and regional lymphadenopathy which dominate the local picture.

The *complications* of oculoglandular tularemia are: (1) suppurative adenitis of the involved lymph nodes, with abscess formation and ulceration through to the skin, necessitating incision and drainage, or surgical removal; (2) occasionally, ulceration of the cornea, with perforation, and prolapse of the iris; (3) acute purulent dacryocystitis; (4) bronchial or lobar pneumonia; (5) hepatitis with enlargement and jaundice; (6) pleurisy with effusion; (7) pericarditis and mediastinal pleurisy; and (8) generalized peritonitis.

While the conjunctival ulcer that marks the original site of entry of infection presents an alarming appearance during the height of the disease, this area heals well, and after recovery only a few faint

striae on the smooth membranous surface, suggestive of a cicatrix, may remain.

The disease is fatal in some cases, in the oculoglandular form as well as in other types. Death occurs in 5 or 6 percent of *all* cases of tularemia—including types other than oculoglandular—reported thus far (to 1944). Francis² has reported a mortality rate of 9 percent in the group of 78 cases of oculoglandular tularemia under his observation, in comparison with a mortality of 6.9 percent in 15,525 cases of tularemia of all types in the United States. It is highly probable that these mortality figures would actually be much lower if *all* the undiagnosed or undiscovered cases (which later recovered) of true tularemia that occur in rural or other areas could be included in statistical reports. Recovery is the rule in man, whereas in the lower animals the reverse tends to hold true. When death ensues, it is due to the septicemia that follows infection, occurring within five days to two weeks after the prodromal period.

The treatment of oculoglandular tularemia is twofold: (1) local, and (2) general. Locally, the instillation of a mild germicidal preparation such as 20 percent neosilvol, or a 1:2,500 metaphen solution, every hour preceded by cold saline or boric compresses may be of help. For general treatment, sedatives, salicylates, rest in bed, mild aperients, and fluids will be conducive to the patient's comfort during the active stage. Foshay⁴ has recently introduced an anti-serum. Although the actual value of serum therapy is still problematical, its use is rational and should be tried, especially in very severe cases, in the hope of preventing the graver complications. Foshay's serum is given in two doses of 7.5 c.c. each intravenously on successive days as soon as a positive diagnosis has been

established. The author recommends the use of nonspecific triple-typhoid vaccine (bacterial vaccine made from *B. typhosus*, and *B. paratyphosus* "A" and "B," Lederle) given intravenously as early in the disease as possible. For adults, an initial dose of 25 million bacteria should be given. The response to this treatment is indicated by the height of the fever and number of chills. After the lapse of a few days the vaccine is repeated, but with twice the amount (50 million bacteria). A third injection of 100 million, and a fourth of 150 million, at appropriate intervals, may be administered. In the case of children, the dose should be adjusted to the age of the patient. A fever ranging from 102° to 105° F. for several hours will usually suffice to produce the effects desired. Artificial-fever therapy has been reported by one observer⁵ to be beneficial. Finally, the use of blood transfusions from a donor who has had the disease and whose serum has agglutinated *B. tularensis* in high titer should be kept in mind, especially in those cases wherein severe complications have arisen and the prognosis is grave. Streptomycin, a recently discovered drug, has been reported to be experimentally effective against tularemia in laboratory animals.

REPORT OF CASES

Case 1. Mrs. A. C., aged 39 years, a white woman, well-developed and well-nourished, the wife of an Army officer, was seen by the author on April 5, 1944, with the complaint that her left eye had been sore for about a week and that the eyelids would swell shut overnight. Examination showed moderate edema of both eyelids, chemosis of the conjunctiva of the lower fornix, and a single, deep, granulomatous ulcer in the conjunctiva of the lower lid. This lesion had been mistaken for a chalazion by a physician. Incision had been followed by a marked

increase in ocular symptoms accompanied by immediate swelling of the left preauricular gland. Examination revealed swelling of the left submaxillary gland, but none in the cervical region at this time.

Inquiry elicited the fact that the ocular distress was first noticed about one week previously, following what the patient termed an "exposure to sneezing by her house cat." While the animal was held on her shoulder, the cat sneezed and projected some of its nasopharyngeal secretion into the patient's left eye. Within three days the eye became itchy, reddened, and inflamed, followed by marked swelling of the lids which caused partial obstruction to vision. Since this was the better-visioned eye of the patient (the right eye being amblyopic), she became very much alarmed.

The cat was an adult female, and had shown signs of being previously ill, characterized by languor, vomiting, and loss of appetite. The animal also had attacks of sneezing, with slight chills, and showed a disinclination to leave its snug retreat within the house. On one occasion, several weeks prior to the incident of sneezing, the pet had been taken to a veterinarian because of the presence of many "open sores" on its belly. These had been removed surgically and were thought by the veterinarian to be ulcerated lymph glands, cause undetermined. The cat recovered from its illness, but later, during the patient's period of convalescence, it suffered another attack similar to, but milder than, the first one.

A more detailed examination showed the cornea and media to be clear, and the fundus negative (the fellow eye remained entirely unaffected). Hyperlacrimation and epiphora were present. Because of the intense edema, the lids were so bulky that handling was quite difficult, and eversion was accomplished only with marked discomfort. Situated in the lower fornix

near the outer canthal angle was a fairly large granulomatous ulcer, raised 1 or 2 mm. above the surface, covered by a yellowish plaque of necrotic tissue, the site of which was much more intensely congested than the surrounding conjunctiva. The presence of a foreign body was ruled out by close inspection, following digital examination of the area from without, and probing of the ulcer from within. Although the preauricular and submaxillary lymph nodes were moderately swollen at this stage, no further regional adenopathy was present. At this time, the constitutional symptoms were not fully developed; the patient complained only of slight dizziness and headache. A tentative diagnosis of Parinaud's conjunctivitis was made, and the patient ordered to remain at home and to limit her activities. Cold boric compresses were applied locally, with salicylates and saline aperients prescribed for internal administration.

A day or so later the patient reported that she was having slight chills and hot flushes, and that she was nauseated. A blood specimen was taken and sent to a local laboratory for examination for possible agglutination reactions to tularemia, but the report was negative. When seen again the inflammatory signs had changed little in appearance, but the preauricular gland had become quite enlarged (about 1.5 cm. in diameter) and was easily palpable and tender. The anterior cervical glands of the middle region of the neck could be palpated. Temperature was 101° F., the pulse 110, and the patient looked toxic. She also complained of sudden weakness upon the slightest exertion. In spite of the negative laboratory report, a presumptive diagnosis of oculoglandular tularemia was made, and the patient hospitalized.*

The first (hospital laboratory) agglutination test made of the patient's blood serum (18 days after the sneezing incident) showed a positive reaction to *B. tularensis* in a dilution of 1:160. A second agglutination test made three days later showed the titer level to be 1:320, indicating the force of the infection to be on the increase. During hospitalization, active treatment was instituted in the form of triple-typhoid bacterial vaccine (nonspecific) given intravenously, with a view to stimulating the formation of allied antibodies to assist in combating the bacteremia. Successive doses of 25, 50, 100, and 150 million bacteria were given. A good response followed with the administration of each dose, manifested by high fever and severe chills, indicating good reactivity on the part of the patient.

As occasion demanded, sedatives and alteratives were given internally to allay the distressing symptoms and malaise associated with the toxemia. The latter progressed with moderate severity during this time, there being short remissions which were followed by recurrences of greater or lesser severity than formerly. Locally, cold boric compresses were applied to the eye, as well as to the preauricular and cervical swellings. The adenopathy meanwhile had become quite extensive, involving finally even the lymph nodes of the left axilla. A colleague was called in consultation when the regional lymph nodes became so intensely swollen and painful that it was feared that surgical incision and drainage would become necessary, but fortunately this was not required.

Within a week after admission, the general adenopathy showed signs of subsidence and resolution. The ocular inflammation had abated: the edema of the lids resolved almost entirely, the conjunctival chemosis disappeared, and the original site of infection presented a moderate-sized ulcer with ragged edges but

* St. Mary's Hospital, Saint Louis.

of much smaller size and showing a reduction in congestion around its base. The patient was discharged after 10 days in the hospital and returned to her home for convalescence.

One of the characteristics of this case was the prolonged period of convalescence. From the onset of illness early in April, 1944, there were periods of recurrence until late in August, 1944, the later attacks marked by decreasing severity. The patient stated that she felt fairly well during the periods of remission, but was unable to perform her normal household duties without extreme fatigue. Restoratives were prescribed during this period, and, in addition, a course of nonspecific foreign-protein (Proteolac) therapy was given intramuscularly. Repeated blood agglutination tests made during the convalescent period showed a decreasing agglutinin titer; the final titer level recorded (August, 1944) was 1:80. Steady improvement followed without recurrence of symptoms, and the patient resumed most of her normal duties without experiencing undue weakness and fatigue. The site of infection in the conjunctiva finally healed completely, leaving little sign or trace of its presence other than a faint, white line.

Case 2. V. W., aged 13 years, a white girl fairly well developed and well nourished, was seen by the writer on November 11, 1944, one week following the onset of a conjunctivitis of the left eye. She complained of persistent soreness and itchiness of the eye, with moderate swelling of the eyelids, which were gummed together in the mornings.

The little patient had recently had a small kitten which died just a few days prior to the onset of the eye trouble. She stated that the kitten had been ill at the time and had experienced several convulsive attacks. She was much affected

by the kitten's illness and while crying, she had inadvertently wiped her eyes after fondling the sick animal. A few days later, her left eye became sore.

There was edema of both eyelids, accompanied by congestion of the conjunctiva, most marked in the upper fornix. There was also present a slight mucoserous discharge. Lying on the palpebral conjunctiva of the upper lid, near the outer angle, was a moderate-sized, raised, yellowish papule, 5 to 7 mm. in diameter, which seemed to be the center of the congested area. No other lesions were present. The cornea and media were clear; the eyeground was normal. The left preauricular lymph node was slightly swollen and tender, but no other regional adenopathy was present. The affection was unilateral.

There was no fever, the pulse rate was not accelerated, but the patient remained at home and in bed. A tentative diagnosis of pneumococcic conjunctivitis was made, but several smears and cultures failed to confirm this suspicion. A blood specimen taken at this time and sent to the laboratory for examination for agglutination reactions to *B. tularensis* was reported negative. For treatment, the eye was given hourly instillations of a 20-percent solution of neosilvol followed with cold boric-acid compresses 20 minutes out of each hour. Sedatives, salicylates, and aperients were given for symptomatic relief.

As the condition progressed, the left anterior cervical lymph nodes became palpable and tender. The preauricular gland had meanwhile become enlarged to the size of a large pea. Also, at this time (approximately 10 days following the onset of symptoms) the child developed a mild fever (99.5° F.) but without chills. She complained of slight malaise and appeared slightly toxic. The lesion now had apparently developed into a fairly

large, granulomatous ulcer with thickened, irregular edges. The yellow plug which filled its center had sloughed off, leaving a raw, intensely reddened crater. Meanwhile, another papule had made its appearance, on the *bulbar* lining of the conjunctiva about 5 mm. posterior to the limbus, and at a site exactly opposite to the first one. This subsequently developed into another ulcer, smaller in size but similar to the first in appearance and characteristics, having a thickened base and covered by a yellow plaque that eventually sloughed off. It was deemed advisable to make another check on the blood-agglutination reaction to tularemia; meanwhile, a presumptive diagnosis of oculoglandular tularemia was made, and the patient hospitalized* for further observation and treatment.

On the day of hospital entry the laboratory report was given to the writer, and this proved to be positive for agglutination reaction to *B. tularensis* in a titer concentration of 1:160. In addition to local and general symptomatic treatment, active protein therapy was instituted, and a series of triple-typhoid (non-specific) bacterial vaccine injections given intravenously, as in the first case of this report, but with the dosage halved. The patient reacted well to the vaccine, responding with high fever and chills. The glandular enlargement soon subsided. Subsequent agglutination tests revealed a decreasing agglutinin titer level: 3d and 4th tests showed positive reactions of 1:80 titer, performed on the 5th and 8th hospital days, respectively. A final test made several weeks after leaving the hospital showed a still lower agglutination titer of 1:40.

The patient returned to her home after a hospital stay of eight days. During con-

valescence the lid edema subsided entirely and both ulcers healed well, leaving no trace of their presence on the conjunctiva. The adenopathy resolved slowly, but the preauricular node remained palpably enlarged for many weeks after the other lymph swellings had disappeared.

Convalescence was slow, but not so protracted as in the former case. Weakness and easily induced fatigue were experienced for several weeks after the patient had left the hospital, but thereafter, restoration followed rapidly and no periods of recurrence were noted. Unlike the patient in the former case, which was marked during convalescence by very many periods of recurrence and remission, this child improved steadily without a single recurrence of symptoms. Restoratives and tonics were given at home to improve the general health. Within three months after the first onset of symptoms, recovery was complete.

Case 3. On March 9, 1945, Mrs. R. M., a white woman aged 23 years, well developed and well nourished, a housewife, came to the eye clinic complaining of a persistent "sore" in the lower lid of her left eye of 10 days' duration. In the beginning, the eye was sore and "itched." Later, on everting the lower lid she observed a moderate-sized lump or "sore" on the inner lid surface. During the days following, her eyelids would agglutinate overnight. Her condition was seen and diagnosed as "pink eye" by her family physician, but as the eye did not improve, and furthermore as her neck had become painful, she reported to the eye clinic at the Trachoma Hospital, where she was first seen by the writer. The first examination revealed a mild degree of edema of the lower lid, with moderate redness of the bulbar conjunctiva and narrowing of the palpebral fissure. The patient's face

*Firmen Desloge Hospital, Saint Louis.

also showed a somewhat anxious expression. When the lower lid was everted, a moderate-sized granulomatous ulcer was found on the conjunctiva, near the outer canthal angle. The surrounding membrane was slightly chemotic, including the adjacent bulbar extension. The iris was of normal luster, and the pupillary reactions intact. The cornea was clear, the eyeground normal. On the left side of the neck, where the patient complained of soreness, there were found to be several enlarged anterior cervical lymph nodes. With further investigation, the preauricular, submaxillary, submental, and axillary lymph glands were also found to be enlarged. A mild fever (temperature 100.2° F.) was present. The patient stated that she had felt somewhat ill for the past week, but ascribed her indisposition to a "cold." She found that she became easily fatigued and did not feel able to carry out her household duties completely.

A search into her present history revealed the following data: Several days prior to the first appearance of her eye disturbance, she had taken care of a sick puppy, aged five months, which had been acutely ill with chills and fever and convulsions for 24 hours previous to its death. When it became ill, the puppy would not eat nor move about, and seemed to be sleepy all the time. The patient nursed the sick puppy, and had noticed that its belly had become "matted" with many lumpy swellings. None of these had ulcerated, however. During the course of feeding the sick animal, the patient admitted that she had often wiped its mouth and eyes with a cloth, and thoughtlessly had also wiped her own eye. Upon being questioned about contact with rabbits (for the patient's family lived in a rural district) her husband stated that about a week or more previous to the

dog's illness he had found rabbit fur scattered all over the yard. This was not unusual, as every now and then a cat or dog living on the premises would catch a rabbit and kill it, sometimes eating its kill, or merely toying with it. He also stated that in addition to this puppy, there was a large female cat on the grounds. Both of these animals would run about freely and hunt or play in the woods near the house. The cat had not been known to be ill at any time, but a blood agglutination test done on this animal later proved to be positive in very low titer (1:10). This cat had several kittens, but none of them was ill. The mother cat later died; she had been sick for many days before death, with symptoms of chills, lassitude, loss of appetite, and distemper. The patient said that she had felt the presence of many lumpy swellings on the cat's belly during its illness. There were two small children in the family, also exposed both to this cat and to the puppy, but neither of them became ill.

A presumptive diagnosis of oculoglandular tularemia was made on the strength of the history and clinical findings. A blood specimen taken at once was examined at the laboratory and later proved to be positive for agglutination to *B. tularensis* in a titer of 1:80. Meanwhile, the patient was hospitalized* and given local and general supportive and symptomatic treatment. For the eye, metaphen instillations and cold boric compresses were used. Ice bags were applied to the preauricular and cervical swellings. Intravenous therapy with nonspecific triple-typhoid vaccine was given in 25, 50, 100, and 150 million bacterial injections. The response to these was fairly good, although the fever rise and severity of chills were not so marked as in the

* Missouri Trachoma Hospital, Rolla.

former instances. During the time of her hospitalization, the patient complained of persistent headache and backache, nausea, and lassitude. Her temperature would vary from 100.8 to 102° F., with frequent chills and sweats. Each exacerbation would leave her weak. After a two weeks' stay she was released from the hospital and ordered to remain at bed rest while at home.

Her period of convalescence was an unusually long one. There were mild febrile symptoms, with occasional chills, and weakness, until seven months after the beginning of infection. During her out-patient visits, the patient complained of headache, dizziness, and easily induced fatigue. Occasionally she would feel well again, but this would be followed in a few days with a recurrence of symptoms which sometimes approached their original severity. A roentgenologic examination of her chest revealed nothing significant to account for the protracted weakness and fatigue, and a constant check was made of her general physical condition.

Because of the protracted illness, the patient was given two 7.5-c.c. doses of Foshay's antiserum intravenously, each on successive days. She reacted with violent chills immediately after receiving the first dose, but otherwise showed no untoward effects. Following the administration of this serum, the patient improved rapidly. Although she still complained of mild febrile reactions in the week following, there were no further signs of chills, sweats, or fatigue. When seen late in the seventh month of her illness, she was found to be well and appeared to be entirely recovered from this infection.

The agglutination reactions showed positive during all this time, in a titer of 1:80 or higher. After the fifth week of her illness, the titer was positive in 1:160,

and remained at this level for many months. The last agglutination test, made seven months after the patient was originally seen, showed a positive titer of 1:160 (October 6, 1945).

During hospitalization and thereafter, the ocular symptoms grew no worse, except that the primary lesion in the conjunctiva had reached and passed its stage of turgescence. The nodular ulcer increased in size and became filled with a yellowish necrotic plaque. This eventually sloughed off, leaving a raw, rough, granulomatous ulcer which healed slowly, but had ceased to be troublesome. Meanwhile, the general adenopathy had not at any time become severe. Although the unilateral preauricular, submaxillary, cervical, and axillary lymph glands had become moderately swollen and painful, there was at no time any question of incision and drainage, nor any sign of abscess formation.

DISCUSSION

The role of the domestic cat as a carrier in the transmission of tularemia was not generally recognized until about 1930. That cats were susceptible to tularemia was noted as early as 1911 by McCoy and Chapin.⁶ Francis⁷ in 1924 infected two cats, one by feeding infected lymph nodes from tularemic guinea pigs, and the other by subcutaneous inoculation with a virulent culture of *B. tularensis*. Both cats died of tularemia. Later, in 1928, Green and Wade⁸ investigated the susceptibility of the cat to tularemia by feeding infective material, and obtained positive results. Simpson¹ in 1929 reviewed the experimental work of Wherry, Green, Wade and Hanson, and that of Francis pertaining to the susceptibility of the domestic cat to infection with *B. tularensis*. Collins⁹ in 1933 reported a case of tularemia in a man, 14 days after he was

bitten on the index finger by a six-months'-old kitten. The cat's serum agglutinated in a titer of 1:80; that of the patient showed a high titer of 1:1,280. Rudesill¹⁰ in 1937 reported tularemia in a woman following the bite of a cat or one of its nursing kittens. The mother cat had fed on a dead tularemic rabbit. A few days later the mother cat and kittens became ill. The mother cat recovered, but the two kittens died. The Public Health Bulletin¹¹ of 1940 reported a total of 13 persons with tularemia after contact with cats, in 2 cases due to a scratch, and in 11 cases due to having been bitten. Shaffer¹² in 1943 reported the following interesting cases of tularemic infection: (a) a patient fondled his family cat, which had been known to have limped for several weeks, and which had a healing ulceration on the skin of the left hind leg. The cat's serum agglutinated *B. tularensis* in a dilution of 1:360. The patient developed tularemia, during which his adenopathy became so severe that the lymph nodes became abscessed and ruptured. (b) Another patient, a boy, was bitten on the left cheek by a domestic cat. The child became ill with nausea, vomiting, and fever several days later. The left cervical lymph nodes became swollen and tender. The blood test showed positive agglutination reaction for tularemia. The cat, a huge animal, was examined but did not seem to be ill and showed no skin lesions, but its blood test showed an agglutination reaction to *B. tularensis* in a dilution of 1:50 (Mulford antigen). (c) A 15-year-old girl was scratched and bitten by the family cat which had been irritable and mean and had scratched and bitten other members of the family. The patient had a slight abrasion on the left index finger where the cat had bitten her several weeks previously. She became subacutely

ill and developed left axillary lymphadenopathy. Her blood serum was positive to *B. tularensis* in a dilution of 1:50. Of the other children who had contact with this cat, one showed a weak positive agglutination reaction, and the other—although her blood test showed negative—developed epitrochlear lymphadenopathy. In this case, although the cat's blood did not agglutinate for *B. tularensis*, it was thought that the patient and her brother and sister were infected from the contaminated animal which itself remained free of infection. The family resided in the suburbs, where the cat was wont to run free and hunt in the fields. Aagard¹³ in 1944 reported the following case: A tularensis-infected rabbit sneezed in the face of a laboratory worker. Although no ocular or glandular symptoms were observed, the patient became very toxic, his temperature rose to 104.6° F., and his pulse to 120. A roentgenogram of the chest showed massive pleural effusion. The serum agglutination tests for *B. tularensis* showed a high positive titer of 1:320. A culture of the patient's pleural fluid revealed *B. tularensis*, and an intraperitoneal injection of this fluid caused death in a guinea pig, with positive autopsy findings of white necrotic foci in liver and spleen.

In the past decade, much light has been shed on the manner of transmission of this disease. Among the various agents now known to be responsible in the transference of the infection to man are: the wild rabbit, beaver, skunk, raccoon, squirrel, woodchuck, muskrat, meadow mouse, rat, fox, coyote, dog, cat, sheep, hog, quail, pheasant, grouse, owl, fish, woodtick, horsefly, deerfly, and other insects. As to methods of transferring infection, Francis² cites contact from wild rabbits through a contaminated hand as first in order of frequency. Other means men-

tioned by him of transferring infection to the eye are by mashing infected tick tissue between the fingers and conveying it to the eye; a fly crushed between the fingers was the cause in another case; contaminated animal blood which spurted into the eye was the cause in two cases; a dog scratch, and contact (while dressing) with a tree squirrel were causes in still other cases.

The greater vulnerability of the conjunctiva to tularemic infection as compared with the unbroken skin is well illustrated not only by the incidences cited by Francis, but also by the last two cases listed in this report. On this point, Francis² mentions that, of 78 cases of ocular infections in the United States, only 6 were accompanied by hand infection concurrently, although the eye and hand in the other 72 cases were subjected to the same source of infection; that is, rabbit tissue, squirrel tissue, groundhog tissue, crushed tick, or crushed fly.

House pets, such as the domestic cat or dog, when kept in rural communities (as in all three cases of this report), may hunt in the fields and thereby become contaminated or infected with *B. tularensis*. The domestic cat's susceptibility to *B. tularensis* has been established, and Francis⁷ has listed the cat among the mildly susceptible animals. When once infected, the cat or dog will show a positive blood agglutination reaction for many years after having been ill; this test, when positive, is conclusive proof of a suspected animal being tularemic.

The strong possibility that sneezing by a domestic cat in the face of the patient was the method of transmission in one case, and that rubbing the eye with contaminated fingers after fondling an infected animal was the method in the other two, must be considered especially since other means of acquiring the infection could not be established. It must be as-

sumed that the mouth and claws of the cat or dog become contaminated by hunting, killing, or eating infected rabbits. In all three instances of this report, the animal became ill, although the adult cat survived in the first case, whereas the kitten and puppy died in the other two cases.

It is regrettable that in all these cases it was not possible to have the animal available for blood-agglutination tests. In the first case, although the cat survived, the patient moved out of state with her pet, and although contacted subsequently by mail in order to secure a specimen for examination, the writer's request was not granted. In the second and third cases, the kitten and puppy had died and had been disposed of before tularemia was suspected; since both the kitten and puppy came of heritage unknown, it was not possible to establish whether or not the parent animals or any of the other litter-mates were infected. The illness of both cats, and of the puppy, although not proved to be tularemia, is in itself a weighty factor to be considered in favor of the probability that the animals were responsible for transferring the infection. It seems reasonable to assume that, in the first instance, the cat's illness was due to tularemia, and that the belly "sores" were a suppurative adenitis; and that its mouth was contaminated with infective material which could have been transferred to the patient's eye during the act of sneezing. With regard to the second instance, the kitten was known to have been ill for several days preceding its death, and during the night on which she kept her vigil with the sick animal, the patient could have transferred infection to her eye by fondling and handling contaminated parts. In the third case, infection could have been transferred to the patient's eye by handling the animal and feeding it while sick.

CONCLUSION

Oculoglandular tularemia, one of the four types of the disease tularemia, although beginning as a local infection of the conjunctiva, can and usually does progress to a state of severe bacteremia evoking a generalized somatic response, characterized by malaise, chills, and fever, and resulting in serious complications. Whether the portal of entry be the conjunctiva, or the skin, once the invading organisms have established themselves in the blood stream, the general response and disease characteristics are the same. In the ocular type, however, the situation is grave because the disease concerns primarily the organ of vision. It behooves ophthalmologists, therefore, to be alert whenever an oculoglandular disturbance presents itself.

The disease known as Parinaud's conjunctivitis is very similar to mild cases of oculoglandular tularemia, and to other oculoglandular symptom complexes. However, Parinaud did not describe bacteriologic findings, and discussed no etiologic factors of his disease. At first thought, it would seem that the cases of oculoglandular conjunctivitis with regional lymphadenopathy which he described were, in fact, cases of oculoglandular tularemia. Gifford,¹⁴ however, believes that Parinaud's conjunctivitis is not identical with oculoglandular tularemia. There is a tendency on the part of ophthalmologists to make diagnoses of Parinaud's disease on insufficient grounds. It is a mysterious disease, and one that is still surrounded by much uncertainty. Vail¹⁵ has referred to it as the *bête noire* of ophthalmology. It is the author's conviction that the two conditions, though similar, are not identical; the greater severity of symptoms of oculoglandular tularemia should distinguish it from Parinaud's disease.

Much doubt can be dispelled, however, by simply making a blood-agglutination test. Ordinarily, the serum agglutinins do not appear in sufficient concentration to yield a positive agglutination reaction before a week to 10 days have elapsed. The test is strongly positive in two to three weeks. A titer level of 1:40 or higher may be considered as diagnostic. In 1932, Foshay⁴ introduced the intradermal test; by its use, it is usually possible to make the diagnosis after the fourth day following onset of symptoms. Smears and cultures of the conjunctival sac are negative because it is usually impossible to cultivate the organisms directly on artificial media. However, washings and scrapings from the conjunctival sac when injected into the peritoneal cavity of the guinea pig will cause death of the animal in 4 to 7 days, if positive. Autopsy findings will then reveal the presence of multiple, minute yellow dots (necrotic foci) scattered throughout the liver and spleen.

SUMMARY

Three cases of proved oculoglandular tularemia have been presented, with symptoms and signs characteristic of the disease, each with a prolonged period of convalescence. In all three cases, a domestic animal (house pet) which had been previously ill was found to have been the closest contact, and therefore deemed to have been the agent of transmission. Although it was not possible to determine positively if the illness of each animal was tularemia because of the lack of agglutination test, the illness in each case was similar to that of other animals known to have had tularemia, and it was thought reasonable to assume that these animal contacts *were* tularemic, and therefore the agents of transmission in the three cases presented.

THE ASSOCIATION FOR RESEARCH IN OPHTHALMOLOGY, INC.

Fiftieth Scientific Meeting

As we go to press, this program has been received, and is inserted here because of its special interest.

PROGRAM

Hotel Mark Hopkins San Francisco, California

JULY 2, 1946

1. THE CYTOLOGY OF CONJUNCTIVAL EXUDATES
Phillips Thygeson, M.D., *Menlo Park, California*
2. MACULAR EDEMA
Arthur J. Bedell, M.D., *Albany, New York*
3. EXPERIMENTAL DINITROPHENOL CATARACT: EFFECTS OF OBESITY, AGE, AND ENVIRONMENTAL TEMPERATURE
Jerome W. Bettman, M.D., *San Francisco, California*
4. CHANGES IN THE ANGIOSCTOMAS ASSOCIATED WITH THE ORAL ADMINISTRATION OF EVIPAL
Austin I. Fink, M.D., *Brooklyn, New York*
5. THE RELATION BETWEEN MATERNAL VITAMIN A, BLOOD LEVEL, AND OCULAR ABNORMALITIES IN THE OFFSPRING
V. Everett Kinsey, Ph.D., Blanche Jackson, Ph.D., and Theodore L. Terry, M.D., Pathology Laboratories of the Massachusetts Eye and Ear Infirmary, and the Harvard Medical School, *Boston, Massachusetts*
6. EXPERIMENTAL GONORRHEAL IRITIS: THE ROLE OF THE LENS IN GROWTH OF THE GONOCOCCUS
Maurice J. Drell, M.D., Marjorie Bohnhoff, M.D., and C. Phillip Miller, M.D., the University of Chicago, *Chicago, Illinois*
7. ELECTROENCEPHALOGRAPHY AND OPHTHALMOLOGY
Alston Callahan, M.D., and Frederick C. Redlich, M.D., Department of Ophthalmology, University of Alabama Medical College, *Birmingham, Alabama*
8. FURTHER OBSERVATIONS ON AQUEOUS VEINS
K. W. Ascher, M.D., *Cincinnati, Ohio*

ANGIOMA OF THE RETINA

REPORT OF TWO CASES WITH FUNDUS PHOTOGRAPHS

OGDEN D. PINKERTON, MAJOR (MC), A.U.S.

Angiomatosis of the retina is relatively rare. The condition is characterized by a vascular growth of the retina followed by exudation, retinal detachment, glaucoma, and other sequelae. When localized in the eye the condition is known as Von Hippel's disease. When accompanied by other vascular tumors of the cerebellum, pancreas, suprarenals, or kidneys the condition is known as Lindau's disease.

During the past three and one-half years about 45,000 eye cases were seen in a large army general hospital outpatient clinic. Two cases of angiomatosis retinae were found. Both occurred in healthy young soldiers, were relatively early growths, and were, as far as could be determined, localized in the eye.

Case 1. A white soldier, aged 27 years, was examined on February 6, 1945. His only complaint was visual fatigue and mild frontal headache when reading. The family history was irrelevant.

Examination revealed: A visual acuity, O.D., of 20/15; O.S. 20/15. The lids, conjunctivas, sacs, corneas, pupillary reflexes, and tension were normal. Fundus study of the right eye disclosed a large pinkish mass about 1.5 disc diameters in size in the inferior nasal fundus into which passed one large dark tortuous artery, and from which a huge dilated dark tortuous umbilicated vein passed upward to the disc (fig. 1). No exudate surrounded the mass. There was no evidence of retinal detachment. The nerve head, macula, and remainder of the periphery were normal. Examination of the fundus of the left eye revealed no pathologic lesion.

Neurologic examination, spinal fluid, blood sugar, intravenous pyelograms, and chest X-ray studies were negative.

Case 2. A white soldier, aged 22 years, was examined on May 15, 1945. He complained of blurred vision in the left eye for the past two weeks. He had been struck in the left eye with a softball about eight months previously, but there

Fig. 1 (Pinkerton). Angioma in inferior retina, case 1.

was no blurring at that time. There were no other complaints. The family history was irrelevant.

Examination revealed: Vision, O.D., 20/15; O.S., 20/40-1. The remainder of the external examination gave normal results. The tension was normal. Refraction with homatropine cycloplegia revealed a mild bilateral compound hyperopic astigmatism. Vision in the left eye was improved to 20/30 with dilatation. With pinhole spectacles the vision was 20/50-1. Fundus study of the right eye disclosed, about three disc diameters above the macula, a large pinkish-white area nearly twice the size of the nerve head. Into this mass passed a greatly

dilated artery, and from it came a greatly dilated tortuous vein about twice the size of the artery. Just below the mass were scattered clouds of exudate which passed into the macular area. Some of the exudate was well organized. There were no hemorrhages. The nerve head was blurred, especially on the temporal side. Binocular ophthalmoscopy with the use of red-free light showed that the mass pro-

chest X-ray studies were negative for abnormalities.

The first case presented was early, and had not produced any local symptoms. It should be an ideal case for surgery (perforating diathermy) or radium therapy. The second case was more advanced, and being closer to the macula produced early visual symptoms. Prognosis for vision in the second case is not good in spite of suc-

Figs. 2 and 3 (Pinkerton). Case 2. Fig. 2, angioma above macula of left eye, showing markedly dilated artery and vein. Fig. 3, showing nerve head and exudate extending into macular area.

jected into the vitreous and consisted of a white delicate spongy tissue spotted by capillary tufts. Venous and arterial pulsation was marked. There was no evidence of retinal detachment (figs. 2, 3).

Neurologic examination, spinal fluid, blood sugar, intravenous pyelograms, and

successful surgery, or successful irradiation because of the proximity of the tumor to the macula.

Both patients reported were subsequently returned to the mainland for further study and therapy.

AMBLYOPIA EX ANOPSIA IN THE ARMED FORCES

GEORGE E. MORGAN, CAPT. (MC), A.U.S.*
Riverside, California

This is a report of 77 cases of amblyopia ex anopsia studied in the Armed Forces. An attempt has been made to analyze the significant factors in each of these cases; to correlate them in a fashion that may stimulate a more favorable approach to therapy of similar groups. I do not know what percentage of all the eye cases seen this amblyopic group presents. Downing¹ recently stated that in the examination of 60,000 selectees "amblyopia was responsible for sixty-six percent of all monocular poor vision." That is a high percentage. The series reported here undoubtedly represents a much smaller percentage of the whole.

The purposes of this report are: first, to arouse in the profession a deeper interest in this problem. Too often the cosmetic aspect of strabismus receives first consideration, and the obtaining of good binocular vision comes off a bad second. The parent's view of the situation often influences the ophthalmologist in his philosophy of strabismus. The need to give early attention to cross-eyed children should be stressed in parent-education programs.

Much of this report is of necessity based upon the history given by the patient. Inaccuracies were to be expected, despite time-consuming efforts to avoid them. However, any of the service men or women who had been annoyed by total occlusion of either eye for several weeks would undoubtedly remember something about it.

Amblyopia ex anopsia is not uncommon. In neurology an analogous situation is described:² paralyzes occurring at birth

or in early infancy may be accompanied by marked interference with the tactile sense. No lesions can be found in any part of the afferent pathway from the recipient organs to the cortical areas. The only explanation offered is paralysis of tactile sensation due to disuse. Response to training is similar to that in amblyopia. This, too, is the only explanation of amblyopia ex anopsia. To carry this analogy further, it is interesting to note that a similar hemiplegia occurring after three years of age will produce *no* astereognosis.

To review briefly, the following characteristics of this type of amblyopia are named: 1. Functional impairment of vision in one or both eyes. 2. No demonstrable pathologic lesion. 3. Vision not improved by correcting ametropia. 4. Strabismus may be associated.

It will simplify this discussion to classify the cases according to the following scheme:³ I. Amblyopia associated with squint. II. Amblyopia associated with anisometropia. III. Idiopathic functional amblyopia.

In one of these groups each of the cases observed will find a place. The type associated with squint or with a difference in refractive error between the two eyes needs no further characterizing. However, there are certain cases of amblyopia in which no cause for the visual defect can be found, even after careful and complete examination. Some of these are due, undoubtedly, to well-concealed organic disorders. It is into this third, the so-called idiopathic group, that 10 to 15 percent of all amblyopias fall. The infrequency of amblyopia when not associated with either squint or anisometropia is most pointedly demonstrated by a review

* Now with Gailey Eye Clinic, 1000 North Main Street, Bloomington, Illinois.

of 400 consecutive nonsquinting eye cases: (1) showing no demonstrable pathologic change; (2) with 1.75 diopters or less in any meridian of either eye; and (3) with visual axes parallel, three patients had less than 20/25 vision in either eye.³ These latter three cases are the only ones which meet all the requirements of group III. The occurrence of amblyopia is seen, then, to be extremely rare.

When this classification was applied to the cases in military personnel herewith reported the following values were found:

<i>Amblyopia</i>	<i>No. Cases</i>	<i>Percent</i>
Strabismic	43	55.9
Anisometropic	23	29.8
Idiopathic	11	14.3

The strabismic patients in this series of amblyopias comprised 55.9 percent of all the cases; 29.8 percent were anisometropic; 14.3 percent idiopathic.

It is interesting to compare the percentages in this series with those in 34 similar cases of amblyopia in children.

<i>Amblyopia</i>	<i>No. Cases</i>	<i>Percent</i>
Strabismic	18	52.9
Anisometropic	12	35.3
Idiopathic	4	11.7

It is evident that the percentages in this group of children correspond closely to those in the amblyopic cases studied in the Armed Forces.

It may be stated, then, that in any large group of amblyopias, about 50 to 55 percent of the cases are associated with strabismus; 25 to 30 percent, with anisometropia; and the remainder, approximately 15 percent, show no obvious cause for the poor vision.

When a case of amblyopia is fitted into one of these three groups—that is, associated either with squint or with anisometropia, or if it is idiopathic—an immediate prognosis of that particular case is possible. The possibility of predicting the response to treatment in each case of

amblyopia is best illustrated by examining a group of amblyopias in children:³

Group I—Therapy of amblyopia showed about 70 percent success

Group II—Therapy about 50 percent successful

Group III—Prognosis guarded

According to this response, 30 cases of the 43 in this military-personnel group associated with squint should have resulted in normal, or nearly normal, vision under proper treatment. Of 23 cases associated with anisometropia, 11 could have resulted in normal vision. Despite the poor prognosis, treatment of the idiopathic group should not be neglected. Fralick⁴ believes that "no amblyopic eye should be considered due to a congenital defect until all forms of occlusion therapy have been used continuously and totally for a period of several months without demonstrable visual improvement."

With the possibilities of visual improvement that have been demonstrated, it is interesting as well as important to examine the histories of these patients. Again it should be stated that a history as given by these older patients is not an adequate basis for criticizing the type of therapy they had received.

- I. Patients under seven years of age seen by physicians... 41.5 percent
- II. Patients under seven years of age for whom occlusion was suggested 9.0 percent
- III. Average age when patient was first seen for ocular examination nine years

In other words, more than one third of these 77 amblyopic patients gave a history of having had a complete eye examination before they were seven years of age. Only one tenth of them recalled having undergone any type of ocular occlusion. Nine years was found to be the average age at which these patients were first seen for their eyes. Perhaps no

criticism should be offered to the ophthalmologists in these cases. Many circumstances may be peculiar to each case. It is interesting to observe, however, that many of these patients could have had good visual acuity in both eyes had it been possible to institute proper early therapy. The late age at which most of these patients were seen constitutes a problem; one that has been approached by a committee studying problems in public schools pertaining to children's eyes. They reported on: "(1) methods of examination, (2) preventive measures, (3) reading problems, and (4) care of patients unable to pay a private physician."⁵ Hunt and Betts⁶ have also reported a study made on a group of grade-school pupils. They believe an urgent need for additional studies exists. When opportunities are presented, the attention of parent-teachers associations and other such groups should be called to this problem of the cross-eyed child.

The subject of proper treatment of amblyopias is not the object of this communication. Briefly to summarize after Gifford⁷ it may be stated that the treatment of strabismus (and this may apply to the other amblyopias) should be started early—Gifford believes as early as one year of age. He suggests full correction under cycloplegia and occlusion of the squinting eye. He assumes that this eye (in monocular squint) is amblyopic. Lancaster has outlined the essential steps to success in treating amblyopia in stating: "A child with convergent strabismus and amblyopia of the left eye first learned to see with the amblyopic eye by occluding the right eye; he next learned simultaneous perception, then fusion, then stereoscopic depth perception on the synoptophore, and, finally, good binocular vision as a habit; i.e., not merely on the synoptophore but in casual seeing."⁸

One of the patients studied in this

series was an enlisted member of the WAC, 33 years of age. She gave a history of having had convergent squint of the left eye since early infancy. At about three years of age she was first seen by an ophthalmologist. Glasses were prescribed. She returned approximately every year for examination. At five or six years of age the right eye was occluded for a period of one half to three quarters of an hour two or three times daily. This schedule was strictly kept for a period of about three months. There was no history of fusion training or surgery.

The eye findings before recent squint surgery were as follows: Vision: O.D. 20/20, correctable to 20/25; O.S. 20/100, correctable to 20/30. Manifest refraction: O.D. +2.25D. sph. \approx +2.25D. cyl. ax. 90°; O.S. +4.75D. sph. \approx +1.75D. cyl. ax. 105°, prism base down.

The visual axes were parallel with glasses; without glasses, there was 16^A convergence in the left eye. Inconstant first-grade fusion was present.

This case is reported because it is similar to several in the group which have received at least partial therapy. It calls attention to one factor that must not be overlooked; namely, the large number of adults in this age group who had received such good therapy, early, that they have not been referred to the ophthalmologist in the Army.

The following table will show an analysis of the 18 cases of amblyopia in children. The original vision, final vision, and months of occlusion necessary are shown:³

RESPONSE OF AMBLYOPIC EYE TO OCCLUSION			
No. Cases	Original Vision	Final Vision	Months of Occlusion
5	8/200 to 20/100	20/30 to 20/20	4 mos.
5	18/200 to 20/100	20/30 to 20/20	3 mos.
5	20/200	20/30	6 wks.

Today, when the stress of social reforms is heavy upon us, it would not be

amiss to encourage some sort of Modern Children's Crusade of our own. It is believed that strabismus is on the increase. This, if true, means an increase in the number of amblyopic eyes, because, as has been shown, 50 percent of these amblyopic individuals have strabismus. The tendency toward an increasing incidence of amblyopia probably is occurring, also, in that group which is due to refractive error. Major Shure,⁹ in reporting 65 cases of strabismus in adults, believes he noted "a definite relation between refractive error and amblyopia." Ophthalmologists should be all the more stimulated to enter upon a crusade against this latter type of amblyopia because of the recent successes in correcting aniseikonia.

The question sometimes still arises of the practical value of prescribing lenses where a large difference between the retinal images of the two eyes exists. Can such patients attain comfortable binocular vision? Briefly, a case reported by Burian¹⁰ might be mentioned, in which was demonstrated what can be accomplished in some of these patients. Burian prescribed eikonic lenses for a patient with the following corrections: O.D. -6.75D. sph.; O.S. +1.00D. sph. \approx -1.37D. cyl. ax. 155°. Comfortable binocular vision was obtained. The good results obtained in this case of high anisometropia convey some idea of what can be done with the 35 percent of amblyopias which fall into this group. The difference in refractive error found in the cases of this series was generally much smaller than in Burian's case.

To summarize and emphasize the favorable response to proper therapy in the type of amblyopias discussed, Zimmermann's¹¹ report of 68 cases is given:

RESPONSE OF GROUPS TO THERAPY

I. Amblyopia associated with unilateral squint in Zimmermann's cases: In 68 cases, 20/20+ vision was obtained in 62 clinic cases studied -91.2 percent. In 18 cases, 20/30+ vision was obtained in 16 -88.8 percent.

II. Amblyopia associated with anisometropia: In 12 cases, 20/30- vision was obtained in 5.

III. Idiopathic: In four cases, 20/30- vision was obtained in one.

SUMMARY

Seventy-seven cases of amblyopia ex anopsia in the Armed Forces have been reviewed. Fifty-six percent of these were associated with strabismus; 30 percent, with a marked difference in refractive error between the two eyes; in the remaining 14 percent no associated etiologic factor was noted. Almost one half of this group was seen by an ophthalmologist before the patient was seven years of age. Less than one tenth gave any history of undergoing ocular occlusion at any time. The average age at which these patients were seen was nine years. Reports of similar cases treated properly in childhood are given. The attention of ophthalmologists is directed to this ocular syndrome in order to stimulate more interest in its early and adequate therapy.

DETERGENTS OR WETTING AGENTS

PHYSICAL AND CHEMICAL CHARACTERISTICS

ROBERT J. ROTH (M.S., ENG.)

Southbridge, Massachusetts

Recently, in a review of contact-lens solutions,¹ it was stressed that one condition essential to the comfort of the contact-lens wearer is the maintenance of a state of dynamic equilibrium in so far as corneal permeability is concerned. When such a state exists, the efflux of water from the corneal cells is equal to, and balanced by, the influx of water into the corneal cells, so that the cornea does not become desiccated by the loss of water or "water-logged" from imbibition of excess water.

With regard to ophthalmic drugs that are administered topically, however, the desired effect is the absorption or influx of the drugs into the cornea. That corneal permeability, as contrasted with permeability of the globe, should be considered is emphasized by Swan and White,² who mention that Laquer, in 1876, demonstrated that absorption into the eye from the conjunctival sac is primarily through the cornea. Pertinent to corneal absorption, Swan and White,² propose the following postulations:

(1) The penetration of drugs into the normal cornea is a complex process the rate of which is determined by factors

similar to those affecting the penetration of other cells.

(2) The molecular structure and resultant physical properties of a drug rather than molecular size affect the penetration rate into the normal cornea.

(3) The physical properties of the drug vehicle, especially the affinity of the drug for the vehicle, may affect the penetration rate of the drug into the cornea.

A survey of recent ophthalmologic literature shows there is a more extensive recognition of the value of using the proper drug vehicle or solvent in which the drug is to be dissolved or suspended. Riser³ discusses tonicity, hydrogen-ion concentration, buffer solutions, preservatives, and surface tension in the evaluation of eye drops and reports that wetting agents which produce increased penetration of the cornea by ophthalmic drugs are the latest trend toward more efficient drops and ointments.

That wetting agents increase the penetration of the cornea by sulfonamide compounds, particularly sulfathiazole, was demonstrated by Bellows and Gutmann.⁴ Using a wetting agent known as zephiran, O'Brien and Swan⁵ were able

to increase the absorption of carbaminoyl choline chloride. For preoperative use, Scholz⁶ suggests the use of a detergent, as less irritating to the conjunctiva, in the cleaning of the lids, brow, and adjacent skin.

Under certain conditions, wetting agents may increase the efficacy of the more commonly used antiseptics by making them more penetrating and more effective. Taub⁷ emphasizes the fact that detergents of specific molecular structures are effective germicides and disinfectants.

An unusual property of detergents that should have a wide field of application in pharmacologic research is the ability of detergent solutions to dissolve otherwise insoluble materials. McBain and co-workers⁸ believe that it is possible to solubilize almost any material in almost any solvent through the presence of a few tenths of a percent of a suitable solubilizing detergent. Two advantages of local application of chemotherapeutic drugs, as listed by Bellows,⁹ are the achievement of a high concentration and the avoidance of systemic toxic manifestations. Bellows describes his use of a few wetting agents as a simple and effective method of increasing the penetrability of sulfanilamide and its derivatives.

Since most drugs in single doses reach a higher concentration in ocular tissues by oral administrations than by local application, and since many drugs may be only slightly soluble in the solvents generally used, the need for further investigation of wetting agents as components of the drug solvent is obvious.

Because there is no reference in ophthalmologic literature to the characteristics and properties of wetting agents, and since their use in ophthalmic therapy will undoubtedly increase, it is proposed here to review the chemical and physical characteristics of wetting agents.

For our purpose, detergents, or wetting agents, may be defined as substances which decrease the surface tension, thus inducing a greater degree of wetting. Detergents, or wetting agents, have also been called cleaning agents, dispersing agents, solubilizers, penetrants, emulsifiers, and surface-active agents. In structure, the molecules of a wetting agent possess a polar (hydrophilic, or water-attracting) portion and a nonpolar (hydrophobic, organophilic, lipophilic, or hydrocarbon group) portion. In the approximate decreasing order of effectiveness, Snell¹⁰ lists the following groups as the hydrophilic portion of the molecule: $-\text{OSO}_2\text{Na}$, $-\text{COONa}$, $-\text{SO}_2\text{ONa}$, $-\text{OSO}_2\text{OH}$, $-\text{SO OH}$, $-\text{OH}$, $-\text{SH}$, $-\text{O}-$, CO , $-\text{CHO}$, $-\text{NO}_2$, $-\text{NH}_2$, $-\text{NHR}$, $-\text{NR}_2$, $-\text{CN}$, $-\text{CNS}$, $-\text{COOH}$, $-\text{COOR}$, $-\text{OPO}_3\text{H}_2$, $-\text{OPO}_2\text{H}_2$, $-\text{OS}_2\text{O}_2\text{H}$, $-\text{Cl}$, Br , I and unsaturated bonds such as $-\text{HC}=\text{CH}-$, and $-\text{C}\equiv\text{C}-$ which, when present in the molecule, promote solubility in water.

The lipophilic portions of the molecule may range from straight hydrocarbon chains to branched hydrocarbon chains and even to modified aliphatic or aromatic rings.

Unless the hydrophilic and lipophilic tendencies of the molecule are well balanced, the efficiency of the wetting agent may be lost, according to Bartell,¹¹ since the portion of the molecule with the stronger character will tend to carry the molecule too completely into that phase for which the solubility tendency is greater. The generalization by Snell¹⁰ that molecular weights of commercial wetting agents concentrate strikingly around 300 ± 50 can be explained by the fact that the individual water-attracting groups are not powerful enough to balance a longer hydrocarbon chain than corresponds to a molecule of this size.

Undoubtedly, the oldest wetting agent

is soap. Today, as many as a thousand patents for wetting agents have been issued. Antwerpen¹² lists about 300 surface-active agents manufactured and commercially available in the United States.

It was Gibbs who first predicted that substances which reduce the surface tension of water will concentrate in the boundaries of their solutions. Later, Hardy proposed the concept that, in lubricating oils, certain molecules so oriented themselves that their "heads" bit into the

thickness, the constancy of the area occupied by the various members of the homologous series of fatty acids; Langmuir concluded, was attributable to the fact that the molecules were standing on end, so oriented that the hydrophilic groups turned toward the water and the lipophilic groups turned away from it. This is shown by Morris,¹³ with the hydrophilic portion of the molecule immersed in water and the lipophilic end projecting into the gaseous phase over the water (fig. 1).

Figs. 1 and 2 (Roth). Fig. 1, Hydrophilic portion of molecule immersed in water and lipophilic end projecting into gaseous phase over water. Fig. 2, Compound whose lipophilic end bears a positive charge.

metal while their "tails" were directed toward the oil. By moving a barrier across the surface of a solution of a surface-tension depressant, Pockels caused a change in surface tension, proving that the molecules of the substance in solution were concentrated in the surface.

Ingeniously measuring the area occupied on the surface of a solvent (water) by different members of the homologous series of fatty acids (that is, $C_nH_{2n+13}COOH$), Langmuir, in his classic studies of monomolecular surface films, showed that the area did not change as the length of the hydrocarbon chain increased. Since the film layer was monomolecular in

A soap such as the sodium salt of palmitic acid, $CH_3-(CH_2)_{14}-COONa$, would orient itself so that the lipophilic portion, $CH_3-(CH_2)_{14}$, projects into the gaseous phase while the hydrophilic portion, $-COONa$, is immersed in the water. The surface of this solution would be oil-like in character. This type of agent, wherein the hydrophilic portion is the positive ion, is called a cationic agent.

Also possible are compounds, the lipophilic end of which bears a positive charge (fig. 2). These compounds are also known as invert or reversed soaps. These wetting agents are best as antiseptics or bacteriostatics. When the hydrophilic portion is

negative, the detergent is known as an anionic group.

Nonionic agents are those whose molecules consist of two nonionizable groups.

Because of (1) the orientation of the wetting-agent molecule, (2) the selective solubility of the hydrophilic portion of the molecule in water, and (3) the lipophilic portion in oils and nonpolar solvents, the interfacial tension between water and the drug to be dissolved, and between the solution of the drug and the cornea, is reduced. Increased corneal permeability to the drug is the consequence of the reduced surface tension.

SUMMARY

Recent applications of wetting agents in ophthalmic-drug therapy seem to warrant investigation for more extensive use.

The physical and chemical characteristics of wetting agents are reviewed.

Two properties of wetting agents that can be used to advantage in ophthalmic-drug solutions and ointments for local administration are: (1) increased solubility of the drug in a solution of the proper detergent permitting a higher concentration of the drug in solution to come in contact with the eye; (2) increased corneal permeability.

NOTES, CASES, INSTRUMENTS

MENINGOCOCCIC KERATOCONJUNCTIVITIS

REPORT OF A CASE TREATED WITH
PENICILLIN

JAMES H. ALLEN, LT. COL. (MC), A.U.S.,
AND GEORGE L. ERDMAN, CAPT.
(MC), A.U.S.
Scott Field, Illinois

Meningococcic conjunctivitis has been observed rarely as a complication of meningitis and even more rarely as a primary infection and then usually during an epidemic of meningitis. Therefore, the following case of a sporadic exogenous meningococcic keratoconjunctivitis, possibly the first to be treated with penicillin, is reported.

A white soldier, aged 18 years, was admitted to the Eye Service of an AAF Regional Hospital because of a keratoconjunctivitis of the right eye. At noon on June 1, 1945, three days prior to admission, the patient had noticed that his right eye was "blood shot." There were no other symptoms at the time, but on the following day there was a slight purulent discharge. By June 3d, although the discharge was not more abundant, there was an increasing redness of the eye and the lids were swollen. When seen in the Eye Clinic on June 4th, all the symptoms had become more pronounced, and, in addition, photophobia had developed.

Examination revealed a muscular young adult male, in excellent physical condition except for the right eye. The patient's head was bowed and eyes were closed in an effort to avoid light. There was a constant flow of tears over the right lower lid and cheek. Both right lids were dull red, swollen, and indurated. There was a slight purulent discharge along the lid margins and a slight pale-

yellow discharge in the lower fornix. The palpebral conjunctiva was bright red on both lids and was thickly studded with follicles, especially over the lower lid. The bulbar conjunctiva was bright red toward the fornices, but in a zone approximately 5 mm. broad surrounding the cornea the color was a deep, purplish red.

Grossly the cornea appeared hazy around the periphery. Examination with the slitlamp and corneal biomicroscope revealed this haziness to be due to superficial stromal infiltration. The infiltration was diffuse in a circular band, approximately 3 mm. broad, with three, round, denser aggregates of the infiltration above between the 10-o'clock and 2-o'clock positions, and four below, between the 4-o'clock and 8-o'clock positions. Each of these aggregates measured approximately 2 mm. in diameter. The corneal surface was intact and did not take fluorescein stain. There were a few fine floaters undergoing thermal circulation in the anterior chamber. The pupil was approximately 3 mm. in diameter but reacted to light.

The right preauricular lymph node was pea-sized and tender.

There was slight injection of the conjunctival vessels of the left eye; otherwise, it was normal.

Laboratory examination. Secretion and scraping smears made at the beginning of the examination were reported by the laboratory to show many gram-negative intracellular and numerous extracellular biscuit-shaped diplococci. Repetition of this examination resulted in the same findings.

A culture was made upon a blood-agar plate and incubated at normal atmospheric conditions, but no growth was obtained from either eye. However, chocolate-agar (starch-base) plates inoculated

* Number of extracellular diplococci encountered in relation to number of WBC counted.

at the same time and incubated in 10-percent carbon dioxide yielded a pure growth of oxidase-positive, gram-negative diplococci, from the right eye. Because of the colonial morphology and rapidity of growth, it was suspected that the organisms were meningococci rather than gonococci. A positive agglutination reaction with polyvalent meningococcic antiserum and the fermentation of both dextrose and maltose were definite confirmatory evidence. A subculture sent to the 6th Service Command Laboratory for typing was reported as *N. intracellularis*, Type I.

A combined secretion and scraping smear was made every hour after the institution of treatment for 13 hours, than at less frequent intervals (see table).

Treatment. The treatment consisted of five intramuscular injections of 20,000 units each of penicillin made at three-hour intervals.

Two drops of 0.2-percent aqueous solution of scopolamine hydrochloride were

instilled during the course of the original examination in order to control photophobia, and the patient was allowed to use cold compresses on the eye for comfort.

Clinical course. The purulent discharge increased from the time of examination until two hours after the first injection of penicillin, then rapidly diminished and disappeared within 12 hours after the beginning of treatment. Swelling, redness, and induration of the lids began to diminish within 24 hours, and the lids appeared normal externally within four days. Conjunctival redness and injection disappeared within five days. The circumcorneal injection faded, and the cornea returned to normal within four days. The right preauricular lymph node was not palpable after the third day. Visual acuity of the right eye was 20/15-2 on the sixth day and fourteenth day following treatment. Visual acuity of the left eye was 20/25, but always had been "weaker" than the right eye.

DISCUSSION

The chief interest of the case was the bacteriologic and cytologic response to penicillin. All smears containing bacteria, made after institution of treatment, revealed a change in morphology, both of the intra- and extracellular organisms. Instead of the typical coffee-bean or biscuit-shape, the cocci were swollen and more nearly spherical. In addition, smears made one hour after the injection of 20,000 units of penicillin showed an increase in the percentage of white cells that had phagocytized bacteria as well as an increase in the number of bacteria within the individual phagocytes. However, phagocytosis diminished rapidly in subsequent smears, but this probably was related to the rapid reduction in the number of bacteria. No bacteria were found in smears made after the fifth hour of treatment. At that time the patient had been given a total of 40,000 units of penicillin. However, treatment was continued until a total of 100,000 units had been given.

SUMMARY

A case of sporadic exogenous meningococcic keratoconjunctivitis that developed at an Army Air Base in the absence of other cases of meningococcic infection was cured rapidly by five intramuscular injections of 20,000 units each of penicillin given at three-hour intervals.

AAF Regional Hospital.

USE OF PENICILLIN IN ACUTE DACRYOCYSTITIS

CHARLES A. TURTZ, M.D.

New York

The favorable reports on the local use of penicillin in external diseases of the eyes have been encouraging. We have recently seen four cases of acute inflammation of the lacrimal sac with all the clinical signs of early abscess formation.

There was also cellular infiltration of the adjacent tissues of the upper and lower lids and cheek. In one case, the infection was so deep seated that it probably involved the periosteum; the swelling of the lids was so marked that the eyes were completely closed, and the lids had to be forcibly separated, so that the eyeball could be inspected. We did not make an incision because there was a history of poorly controlled diabetes. This infection cleared up completely with the local use of penicillin.

CASE REPORTS

Case 1. Mrs. A. S., aged 52 years, a housewife, consulted me on May 2, 1945, with a history of tearing and secretion from her left eye for the past three years. This had been treated at irregular intervals. She gave a history of uncontrolled diabetes, also occasional head colds that aggravated the tearing. Her physician claimed that her nose and sinuses were entirely normal.

The patient stated that about 10 days before her first visit, there had been a great deal of redness and swelling in the corner of her eye which spread to her eyelids and cheek, and was accompanied by moderate pain, cervical adenitis, and a slight rise in temperature. She was treated by her physician with drops and hot applications, but the condition became steadily worse.

On examination, there were all the clinical signs of early abscess of the lacrimal sac, and a mucopurulent secretion was easily expressed from the lower punctum. A smear showed the preponderance of staphylococci. An examination of the eyeball revealed marked injection of the tarsal and bulbar conjunctiva. The media were clear. The fundus showed no pathologic change except some fullness of the retinal veins.

The infection probably involved the

periosteum, and although incision and drainage were indicated, I was reluctant to operate because the patient had given a history of poorly controlled diabetes.

Local applications of hot magnesium sulfate were advised. When she returned in 48 hours, she said that the pain had subsided slightly, but the redness and swelling remained unchanged. A 2-c.c. solution of penicillin (1,000 units to 1 c.c.) was instilled into the lacrimal sac. There was some regurgitation from the punctum. The same solution was prescribed, 2 drops every 2 hours. This treatment was accompanied by the application of local heat.

When the patient returned two days later, the pain, redness, and swelling had noticeably subsided. The same dilution of penicillin was instilled into the punctum, and the use of penicillin was continued for three more days. At the end of that time, there was such marked improvement that the instillation of penicillin was repeated and the patient advised to continue the use of penicillin three times daily for one week. By the end of that week, the redness, tearing, and swelling had completely cleared up. Penicillin was again instilled, and there was some regurgitation from the punctum. The therapy was then discontinued. On her last visit (June 11th), there was no indication of any previous infection; the area over the lacrimal sac and the adjacent tissue appeared entirely normal, and there was no tearing.

Case 2. Mr. A. J., aged 55 years, a jeweler, consulted me on April 11, 1945, and gave a history of tearing from his right eye during the past two years. This would become aggravated during the winter months. A complete physical examination by his physician, including nose and sinuses, was entirely negative.

For the past three weeks, following a head cold, the secretion had become thickened and was accompanied by pain, redness, and swelling over the area of the

lacrimal sac. The first examination revealed all the clinical signs of an acute purulent dacryocystitis. The area was sensitive to the slightest pressure. A smear taken showed the preponderance of staphylococci. The eyegrounds were entirely negative.

Penicillin solution (1,000 units to 1 c.c.) was instilled into the lacrimal sac. There was some regurgitation. A solution containing 500 units per 1 c.c. was ordered instilled every three hours, in addition to local hot applications of magnesium sulfate.

When the patient returned after three days, the redness and swelling were greatly diminished. The instillation of penicillin was continued. One week later, the redness, pain, and swelling had subsided completely. Penicillin solution was discontinued at the end of 10 days.

A reexamination on April 30th, showed the area over the lacrimal sac to be normal in appearance. There was slight tearing.

Case 3. Mrs. L. B., aged 59 years, a housewife, was first seen on June 4, 1945. She gave a history of tearing from the right eye at irregular intervals during the past year. She had received treatments (probing) which cleared up the tearing temporarily. About 10 days prior to her visit, the area over the lacrimal sac had become red and painful. This was accompanied by a thick, yellowish secretion.

On examination, I found all the clinical signs of an acute dacryocystitis. A smear taken showed a mixed infection—staphylococci and a few streptococci. The same procedure (used in cases 1 and 2) was employed; that is, instillation of penicillin (1,000 units to 1 c.c.) and local heat applications. Two drops of penicillin solution, 500 units to 1 c.c., were ordered instilled every two hours.

Three days later, the redness and swelling were reduced; within a week, this had

completely subsided, and the use of penicillin was discontinued. There had been no recurrence when this patient was last seen on June 19th.

Case 4. Mr. A. L., aged 63 years, a business man, consulted me on August 14, 1945, with a history of pain, redness, and swelling over the left lacrimal-sac area for about two weeks. He gave a history of tearing from that eye during the past year with occasional treatment (probing) without receiving any relief.

An examination showed all the usual signs of an acute dacryocystitis. There had been a spontaneous perforation the day before his visit, and a sinus resulted over the area of the sac.

Penicillin solution (1,000 units to 1 c.c.) was instilled, and penicillin ointment (1,000 units to 1 gram) was ordered applied every three hours to the inner canthus to the area over the sinus.

Three days later, the redness and swelling had subsided greatly. The instillation of penicillin was repeated, and the use of the ointment was continued at less frequent intervals for about two weeks.

This patient was kept under observation for several weeks. The instillation of penicillin was discontinued as soon as the redness and swelling over the sac had subsided, but penicillin ointment was continued until the sinus had completely healed over. The last examination, on September 10th, revealed no evidence of any previous inflammation of the lacrimal sac; some tearing persisted, however.

CONCLUSION

Four cases of lacrimal-sac inflammation with early abscess formation have been reported. In one case, an incision was not deemed feasible, due to poorly controlled diabetes. In the other cases, incisions were not made because the swelling was hard to touch and not localized.

Smears taken showed the preponder-

ance of staphylococci, and, after the inflammation had subsided, the bacteria were less numerous. The same procedure was employed, instillation with no attempt at irrigating the sac. The use of penicillin solution or ointment was prescribed. Ointment was obtained more easily than the solution. The results were excellent.

All patients were healthy in appearance, although each one gave a history indicative of a former infection of the sac or stenosis of the nasolacrimal duct; their general health was excellent.

While I realize these cases are limited in number and that penicillin is not a panacea for all lacrimal-sac infections, I believe these results prove that further study would be justified. When local treatment is indicated, the employment of penicillin has proved of value, at least in ameliorating the symptoms of acute inflammation of the lacrimal sac.

65 Central Park West.

INDIVIDUALLY MADE ACRYLIC MOIST-CHAMBER SPECTACLES AND PINHOLE GLASSES

JOSEPH W. HALLETT, CAPT. (MC),
A.U.S. AND SAMUEL PITTLER, CAPT.
(DC), A.U.S.

Drew Field, Florida

Condensation chambers and pinhole glasses each require an accurate fit to the contour of the face around the eyes, the former in order to obtain an air-tight seal and the latter to prevent light leaks. The presently used types of chambers, shields, and glasses do not satisfy this requirement too well. It is accomplished, however, by a new kind of appliance to be described.

The prevention of evaporation of tears from the corneal surface whenever inadequate closure of the eyelids exists, as in Bell's palsy, exophthalmos, burns, and traumatic defects of the lids, is a well-established therapeutic principle. It is

similarly desirable to avoid minor injury to the cornea when it is analgesic or hypesthetic; as, for example, in neuro-paralytic keratitis, herpes simplex corneae, and Fuchs's epithelial dystrophy. For all these purposes various types of shields and chambers have been devised.

Fig. 1 (Hallett and Pittler). Acrylic plastic chamber processed around lens and frame of patient's glasses.

Perhaps the most commonly used and probably the simplest and cheapest to make is a cone of washed X-ray film, the base of which is cut to approximate roughly the contour of the face around the eye, which is then attached to the skin and made airtight by strips of adhesive plaster or Scotch tape. The disadvantage of this type of shield and similar commercially made celluloid, glass, or plastic ones is that the adhesive strips inevitably become wet and soiled and loosened so that the air-tight seal is broken. Frequent redressings are therefore necessary, and these usually induce considerable skin irritation.

In the handling recently of two severe cases of herpes simplex corneae, it was decided, as has long been advocated by Lloyd,¹ to make use of a protective shield during the patients' lengthy con-

¹ Lloyd, Ralph I. Personal communication to the authors.

valescences. Being aware of the disadvantages of other types of shields, we found most desirable an acrylic plastic chamber processed around the lens and frame of the patient's glasses (fig. 1). Very accurate air-tight contact with the face is obtained (fig. 2) by working from an impression, similar to that for a dental prosthesis, of the entire orbital and periorbital areas of the face. The end product is durable, light in weight, crystal clear, and rather inconspicuous. It is moisture-proof, easily cleaned, and can be removed and replaced as readily as a pair of ordinary glasses. Droplets of moisture can be seen to form inside the chamber within five minutes after its application. Skin irritation is kept to a minimum by the avoidance of adhesive strips. Any dental technician capable of processing an acrylic denture can easily reproduce this type of chamber.

The first step in the production of the chamber is the preparation of the patient's face for an impression by applying a thin layer of petrolatum to the eyelids, brow, and the periorbital area of the face. The lids are kept closed, and the eye is protected by a small wad of cotton or gauze placed over the lids. The lens is removed from the patient's Government-issue, commercial type, metallic frame spec-

Fig. 2 (Hallett and Pittler). Showing accurate, airtight contact with face.

tacles, and a soft wax is painted on the nose pads and on all parts of the frame that touch, or come very close to, the face. The frame is placed upon the pa-

tient's face, the wax adapted, and, if necessary, more wax is applied. The patient is then told to relax his facial muscles so that the impression will conform to the most normal contour. With the frame in position an impression is taken with an alginate base powder.² An impression tray for holding the material may be made from dental wax. After the material has set for five minutes it is removed from the patient's face.

Dental stone is poured into the impression. After the stone has hardened, the impression material is removed from the stone model and from the frame which remains in position on the stone model. The case is now ready to be waxed.

The base of the wax model is made on the stone model to correspond to the area of contact between the finished appliance and the face. In order to obtain an airtight seal the stone model is scraped to a depth of 2 mm. and a width of 4 to 6 mm. in all areas except that already covered by soft wax where the frame touches, or comes very close to, the face. The rest of the wax-up from the base to the frame is made of a single thickness of dental pink base plate wax, the temple of the frame being kept just clear of the wax.

Upon completion of the wax model, dental stone is poured through the opening in the frame where the lens has been removed. Enough stone should be used to make it flush with the rim of the frame. The temple of the frame is removed and the model is half-flasked by investing it in plaster of Paris. It is then tin-foiled before being full-flasked. After the plaster hardens, the flasks are separated; the wax is removed with boiling water; and the other half of the flask is tin-foiled. Then clear acrylic denture material is pressed into position to take the place of

the wax, and the flask is again closed and boiled for 30 minutes. Upon cooling the case is removed from the flask; the stone and plaster are removed from the appliance; and the latter is cleaned, pumiced, and polished.

To permit the replacement of the lens in the frame, the appliance is cut through cleanly along the line where the temple of the frame will rest against the appliance.

Fig. 3 (Hallett and Pittler). Pinhole glasses fitted tightly and accurately to the face.

The lens and temple are replaced. The cut is sealed by a relining acrylic, which now will also cover the temple, if so desired.

The spectacles are placed on the patient's face. Any poorly approximated areas may be filled in with reline acrylic or ground down, as the case may be. A generally loose fit can usually be remedied by adjusting the fit of the temple around the ear.

A further use for this type of appliance was suggested by the need for pinhole glasses in the postoperative treatment of a case of retinal detachment. The ordinary commercial type of pinholes does not fit accurately to the face and, as a result, permits light leaks to occur. Such leaks may be completely avoided by the accurate apposition of acrylic chambers to the skin around the eyes (fig. 3). The acrylic can easily be made opaque by the addition of a little charcoal powder. The area where the lens is situated in the moist chamber is replaced by acrylic in which the pinhole is drilled upon completion of the appliance. If a large enough flask is obtainable, both pinhole chambers

² We have used Coe-loid powder, a product of Coe Laboratories Inc., Chicago, Illinois.

can be prepared at the same time; otherwise, the nosepiece of the frame can be cut with a separating disc and both halves of the glasses individually prepared and then reunited by soldering the nosepiece.

Further adaptations for and changes in the appliances may suggest themselves in individual cases. To date in our cases they have proved to be most satisfactory.

A.A.F. Regional Station Hospital.

SYNTROPAN AS A MYDRIATIC*

WERNER BAB, M.D.
San Francisco, California

My last report¹ on syntropan in 1942 dealt with several attempts that were made to exclude the burning sensation of syntropan solutions to be used for diagnostic mydriasis. Syntropan (Hoffmann-LaRoche) is the phosphate salt of 3 diethylamine, 2,2 dimethylpropanol tropic acid ester. Its main effect is parasympathetic, and its internal uses are chiefly the same as those of atropine. Its advantages as a mydriatic were then described: the rapid effect; the short duration; no general dangers nor discomforts; no local dangers, as damaging the corneal epithelium, or increasing the intraocular pressure; no delay in returning to work for the patient.

These advantages have been confirmed during the last three years. For lack of time, many patients did not want to wait in the office for dilation for an hour or two, and were inconvenienced by being unable to go back to work immediately after the examination. Strictly speaking, syntropan never irritated the eye, but the burning sensation often caused a flow of tears that delayed the effect of the mydriatic by washing away part of the instilled drops.

Recent developments. The following

*From the Department of Ophthalmology, Mount Zion Hospital.

observations result from experiences with more than 300 cases. The exact measurements (ruler or strabometer) of pupillary size have been regularly taken since 1942. All solutions were buffered according to the prescriptions of Gifford.² A solution that was buffered and made isotonic with tears at the same time promised to be most satisfactory. In 1943, a solution was prepared[†] that was based on a recent research of Arrigoni and Fischer³ who postulated that ophthalmologic solutions should be isotonic with tears, and that the pH should be adjusted within narrow limits of the lacrimal fluid, if a nonirritating collyrium was to be prepared (pH of tears about 7.4). But these authors stated that a solution within the pH range of 6.5 to 7.8 was nonirritating, if the collyrium was isotonic. The freezing point of tears was stated to be equivalent to that of a 1-percent solution of sodium chloride, which lowered the freezing point by 0.8°C. Accordingly a 4-percent syntropan solution (sol. no. 7) isotonic with tears was prepared. The freezing-point depression was 0.822°C., close to the requirement. But it was not possible, we were informed, to obtain a stable syntropan solution with a high pH. The pH of this solution, therefore, was 4.33. Even this low figure showed a very slight diminution when the solution was allowed to stand for a month or more. A local pharmaceutical laboratory also stated that it was impossible to have a stable syntropan solution prepared that had the necessary high pH. As this solution was "burning" again, as was anticipated, I returned to previous efforts to make syntropan non-burning, by incorporating an anesthetic.

A new 4-percent solution (sol. no. 8), isotonic with tears and with a pH of 4,

† William T. Strauss, M.D., of the medical department of Hoffmann-LaRoche, was helpful in having this and several other syntropan solutions prepared. For their interest in these tests I wish to thank Dr. Strauss and his co-workers.

that contained 1-percent. holocaine, was prepared and used for half a year. Only the first drop burned, the following drops did not. Mydriasis was satisfactory after 25 to 35 minutes. In dark-complexioned persons its effect was usually delayed for 10 to 15 minutes. For slitlamp examination one or two more drops had to be given, and the period of waiting was slightly extended. But the dilatation was never such that the pupil did not contract with the strong light of the slitlamp (retained light reaction of the pupil with the 4-percent solution).

For these reasons the use of a stronger and more efficient solution was taken under consideration, also the return to a higher pH, if possible. The idea of making the solution isotonic with tears was abandoned to stress the higher pH. A local pharmacy prepared a 6-percent solution (sol. no. 9), and with a pH of 6.6. This solution was more satisfactory. One drop of an anesthetic was instilled before the solution was used, but this was soon abandoned as unnecessary. The desired effect, except in dark-complexioned persons, was faster than with the 4- or 5-percent solution. After two months, the patients began to complain again about burning. Since I knew that the high pH of this solution was dangerous to its stability, its pH was examined and found to have dropped from 6.6 to 6.2. Although this change of 0.4 was small, the figure of 6.2 was lower than 6.5, the limit allowed by Arrigoni and Fischer.³

Recent findings. A new solution was prepared again with a pH of 6.6 and in a 6-percent strength (sol. no. 10). This has now been used for four months and has not lost its stability so far. Its pH will probably go down after a time, as has been the case with all previous solutions. With this restriction the findings are now: (1) A 6-percent solution is better than the previously used weaker solutions. The use of the slitlamp is possible

because the light reaction is negligible. (2) Retinoscopy can now be done to an extent that was previously never considered. The amount of the cycloplegic effect varied between 1 and 2 diopters after one-half to one hour. If there is a doubt about the retinoscopic values, the addition of one more drop of syntropan and waiting a few more minutes make the results more dependable. Previous reports that claimed that syntropan would not affect the accommodation are therefore not exact. Concentrations of 1 or 2 percent never result in any measurable cycloplegia, whereas 4- and 5-percent concentrations do. The 6-percent solutions have a definite and rapid cycloplegic effect, measurable by comparing the lens power at which 14/14 A.M.A. rating print is easily read at near distance. (3) Even the use of five drops of this 6-percent solution had no tension-raising effect (measured with a Schiøtz tonometer). Since I started to use syntropan (in 1934) no glaucoma has been induced by it. It was, however, never used in any case of a suspected or manifest glaucoma. After the cycloplegic properties were found, it was considered not safe enough to press the point as to the nontension-raising properties of syntropan. It probably depends on the concentration whether this effect will be present or not.

Present procedure. (a) Usually a drop of an anesthetic is instilled first. (b) Three to five drops of 6-percent syntropan are instilled at 3- to 5-minute intervals. Each case is handled individually according to the time available, the rapidity of dilation, or the needs (diagnostic mydriasis only, or slitlamp examination also). (c) Routinely, one or two drops of 2-percent pilocarpine are instilled before the patient leaves. This brings the pupil back to its original size within 20 minutes. Fresh solutions burn less than solutions allowed to stand longer. Because of the burning of older solutions, more tearing

results, and with it more syntropan escapes. Thus the loss of time through initial instillation of an anesthetic is compensated by the more intense effect of the syntropan without excessive lacrimation.

Details of the mydriasis. If the interval of three drops given is three minutes each, the mydriatic effect is faster than when the interval is five minutes. The average dilatation following instillation of the 6-percent solution (three drops at intervals of three minutes) is a pupillary diameter of 7 to 8 mm. after 25 to 30 minutes. After 15 minutes the pupil is usually not wider than 4 mm.; 35 to 50 minutes after the first drop, the pupil is dilated 8 to 9 mm. in size.

Synergistic effect of neo-synephrine. When the 2.5-percent ophthalmologic solution of neo-synephrine was introduced, I tried it for diagnostic dilatation. The complaints about burning reminded me of my experiences with syntropan. Therefore, an initial drop of an anesthetic had to be instilled. It had been recommended for synergistic action combined with a cycloplegic. Although it was claimed that the adrenalin-like drugs affect the accommodation too, there was never any proof of it in my experience. There was no cycloplegic effect from neo-synephrine alone in the doses and concentration I used. But as 6-percent syntropan had such an effect, both combined induced both an excellent mydriasis and a certain amount of cycloplegic effect.

The procedure with the combined use

of syntropan and neo-synephrine is now as follows: (a) One initial drop of an anesthetic. (b) After three minutes one drop of neo-synephrine. (c) Continuation with syntropan as described above. In dark-complexioned persons, or if the desired effect of a rapid mydriasis does not take place, each following drop of syntropan is accompanied by one drop of neo-synephrine. The combined use of both drugs hastens the mydriasis, and makes the pupil 1 or 2 mm. larger within the same period of time that syntropan alone would accomplish.

CONCLUSIONS

To the previously mentioned advantages of syntropan as a mydriatic the advantage of using it for retinoscopy in adults may be added. I have recently used stronger solutions than in previous years. The effect of syntropan was proved to be that of a real cycloplegic (which is true of all the members of the atropine group). Therefore, I am now reluctant to recommend it further, in 6-percent concentration, as not dangerous in cases of suspected or manifest glaucoma; in such cases it is definitely contraindicated.

Syntropan is, therefore, an excellent mydriatic. It is recommended that the solutions be renewed from time to time to avoid the change in the value of the pH and the burning sensation connected with this change.

SYMPOSIUM ON SCREENING METHODS FOR EYE DEFECTS

SCREENING TECHNIQUE FOR EYE DEFECTS IN THE ARMY

MAJOR J. INCIARDI described the administrative and ophthalmologic procedure followed in the determination of ocular fitness for military service as practiced at the Armed Forces Induction Station in New York City. This mass examination is for the purpose of procuring men for military and limited service. A complete scientific ophthalmologic examination could not be performed because of certain limitations as to time, space, and administrative necessity. Overnight stays and hospitalization had to be kept down to a minimum, and it should be emphasized that the ophthalmologic examination is only a small part of the complete examination for which the men are called, and which is done in one day.

The procedure is facilitated by dividing the subjects into two tentative groups, normal and abnormal. The abnormal is selected on the basis of eyeglasses, history of having had eye trouble, statement of poor sight in either eye, and so forth. The normal group comprises about 75 percent of those examined, but only a quarter of the examiners are assigned to this group. The visual acuity is tested at 15 feet on a Navy chart having several lines of 15- and 20-foot letters, the examiner facing the testee. If these are missed, indicating a vision poorer than 15/30, the testee is

shifted to the abnormal group. An external examination is performed. When the ocular rotations are tested, the examiner looks for the edge of a possible contact lens, and for the same reason, he keeps in mind a deep anterior chamber. Ophthalmoscopy is also performed.

The abnormal group is examined for manifest refraction, the poorer eye, as determined by history and the strength of the glasses worn, having its visual acuity determined first. A projector chart is used. Refraction is performed with cycloplegia, if indicated. The objective findings and subjective vision are reconciled. Where there has been an enucleation, the history is recorded. Controversial or borderline cases, where there is diplopia, epiphoria, or questionable malingering, are referred to the head of the department. Two examiners go over all controversial cases. There are fewer malingerers than is customarily believed.

The constancy of the technique is indicated by the day-to-day relative uniformity of the size of the different groups into which the testees are finally divided on the basis of the examination. That few cases unsuited for induction are overlooked and passed is indicated by the very small number of eye defects in men discharged from the Army for preëxisting defects in general.

Discussion. Dr. Morris Davidson pointed out that in the last war 3 percent of the inductees were rejected because of eye defects. Subsequent to induction, 1 percent had to be discharged because of preëxisting defects which had not been discovered. He asked what percentage of defects are overlooked by the technique now used.

Dr. J. J. Fried inquired about the number of cases of squint seen, and how these cases were considered from the viewpoint of induction.

Major Inciardi, in closing, said that statistics are not available to answer these questions directly. There has been a report from an Army hospital in California, where of 7,000 men discharged from the Army because of eye defects, 23 had defects involving the eyes; but it was not stated how many of these were present prior to induction. As the New York City induction station shows the same proportion of rejected and passed candidates as other stations, it may be assumed that it is not overlooking more defects than the others.

As to squint, there were so many qualifications that it was decided not to list strabismus at all except where it was rejectable, and, since for statistics one general diagnosis was made, the figures available do not give a true picture of the number of cases seen. With good vision, up to 30-degree strabismus was acceptable.

TECHNIQUES FOR SCREENING EYE DEFECTS AMONG INDUSTRIAL WORKERS

J. H. COLEMAN, PH.D., discussed screening technique on the basis of the experience at the Sperry Gyroscope plant. Before an appropriate screening procedure can be established for an industrial worker, it must first be known what constitutes a visual defect for him. A formidable difficulty has been that by most arbitrary definitions of eye defects many proficient industrial workers have defective vision, some bad enough to disqualify them on the basis of those definitions. In that event, the quality of the visual fitness of an industrial employee would not appear to be sufficiently important to management to warrant the cost of systematic eye care and study for its employees. This,

however, is as absurd as to think that most industrial workers have the best vision that modern professional knowledge can provide. The facts are the reverse. A high proportion of industrial workers are in need of eye care but do not get it. It pays to maintain the workers' good vision, for their skill becomes greater as they grow older.

In this plant, evidence was found that has convinced management of the worth of a systematic eye-care program by attacking the problem from a different point of view. Assuming that satisfactory workers have the various attributes requisite to performing the job, we set out to learn wherein their visual skills differed from those of the less satisfactory employees on any given job. The tests are performed on the ortho-rater, and the patterns of visual skills for successful workers varied with different types of jobs. This method has not only revealed a marked relationship between visual skills and success on the job but has provided practical standards for screening eye defects. In fact, this method was the foundation upon which a dynamic industrial eye-care program has been built. Standards were set up by which applicants could be selectively placed at jobs in which their vision would give them the greatest likelihood of success, other factors being equal. This method of screening indicated that one fourth of the workers were in need of professional eye care.

Discussion. Dr. Laurance D. Redway indicated that testing for stereopsis is fraught with pitfalls. Many workers, successful on a particular job, will lack the degree of stereopsis accepted as standard. They will have developed some other function to take the place of the stereopsis. Adequate depth perception, permitting the operation of even fine machines, may be found in workers who show some suppression, indicating that there are sub-

stitutes which can be used advantageously.

Miss Edith C. Kerby said that the National Society for the Prevention of Blindness can function in a program of screening through its library facilities and its consultants. She emphasized that the ophthalmologist should bear in mind that a screening process is not diagnostic in nature. The work is done by technicians who have learned to handle an instrument very accurately but are not trained to draw conclusions. The ophthalmologist is needed for guidance and interpretation and should assume a coöperative and understanding attitude toward this work.

Dr. Morris Davidson said that many ophthalmologists are unfamiliar with the term "screening," which is simply another word for sifting, which, in turn, is a means of classification. A group may be broken down into two or more subgroups, but neither a double nor a triple sifting will accomplish anything of value unless it is performed for a purpose—not the sifting itself, but what is done about the findings, is the objective. As had already been indicated, the purpose of the screening is to determine what the individual is visually qualified and prepared to do. Full employment is hoped for after this war, but if everyone is to do a job, the problem is to learn what he can do and whether he has the specific visual requirements for any particular job to which he may be assigned. Although central visual acuity alone has been taken as an index of visual skill, it is not valid to assume that skilled performance is related to visual capacity in terms of visual acuity alone. Moreover, workers acquire their skill with differing degrees of effort, and unless we divide skilled workers in accordance with the years of acquisition of their skill, we may overlook factors other than visual.

Dr. James W. Smith said that if these

tests are to be performed by technicians, the employee should be informed that his eyes are being tested only for job placement and skill, and the test should not be regarded as a medical eye examination. Many workers might pass this battery of tests despite the presence of a pathologic eye condition which they might then neglect, having been assured their eyes are "all right."

Dr. Coleman said that the ortho-rater, the instrument used for his tests, determines the visual acuity of each eye separately and together, depth perception, vertical and lateral phorias, and color perception, at the near and far distances. The instrument is portable and can be taken into the factory or wherever desired, an important consideration to keep to a minimum the time the worker is off his job. It takes about seven minutes to test a single employee.

Dr. Percy H. Fridenberg said that screening alone is just a little corner, one detail among many in the field of ophthalmology applied to industry; that Dr. Coleman had brought out an important point in stressing visual skill as something more than the ability to read a certain line on a test chart at a given distance. Total fitness is what we want to determine, and this involves many ocular as well as "extraocular" functions; namely, color vision (of prime importance in many pursuits), depth perception, prompt and accurate reaction, and correct response to the visual stimulus. The tactile sense may greatly aid or even supplant defective vision in such near work as measurement of tolerances and screening (that is, sifting) minor defects of material. Concentration in the act of seeing may not be susceptible to quantitative measurement but is of great importance. Here, as in so many other activities, experience is a factor, and performance tests will take the place of many purely functional examinations. All

this is part and parcel of our machine age, the rapid and increasing progress of technology, and the mechanization of industry that has revolutionized the processes of production, especially inspection measurements and the automatic elimination of substandard parts. This mechanization, it need hardly be pointed out, finds perhaps its most striking expression in war, not only in combat, but in logistics, transportation, spotting, range-finding, and reconnaissance by a number of specialized photographic and photoelectric processes. In aviation, the speed of up-to-date planes and of the latest weapons—rockets and self-propelled bombs—is so great that the eye cannot pick up, to say nothing of following, the flying target. As this speed approaches that of sound, the noise of the enemy engines does not reach the "spotter" as a warning signal but is more often a death notice, after the damage has been done. Complicated calculations are required for range finding, aiming, and firing, taking into consideration the many variable factors involved, and all this is now done by remote control by an apparatus which does the seeing as well as the split-second thinking. The eye has been relieved of many duties, but other important ones remain.

MASS EXAMINATION OF SCHOOL CHILDREN

DR. MOSES FREIBERGER said that the Department of Health of New York City established its first eye clinic to service the school child 28 years ago. An average of 10,000 new cases is now seen annually. An analysis of the statistical data obtained is outside the scope of this presentation. Every child has a vision test before entering school; and twice yearly thereafter the teacher tests his vision again. In one study, the accuracy of the teachers was checked, and it was found that they were accurate in 95 percent of the cases with a

visual acuity of 20/50 or poorer. With vision of 20/40 or better the teachers were correct in only half the cases. The latter cases are retested by the school nurse. Children with vision of 20/40 or worse, or with eye symptoms, are referred to the ophthalmologist.

In the Department of Health Eye Clinics, the doctor records the visual acuity, muscle balance, color test, and any other external findings. The nurse then instills a 2-percent solution of homatropine, although it is realized that atropine is a better cycloplegic. Certain experiences with the latter, which must be instilled at home, led to its discontinuance for the mass testing. Retinoscopic findings and any ophthalmoscopic abnormalities are now recorded. Eyeglasses, if needed, are prescribed at the postcycloplegic test. A return visit is required to check the glasses, and a periodic return every six months or a year is required for the remainder of the child's school life.

The Board of Education maintains 102 sight-conservation classes to which children with corrected vision in each eye of 20/50 or worse are recommended, as are also children with myopia of a reasonably high degree. The teachers are specially trained and have taken a prescribed course in ophthalmology. The classrooms are selected to give the best possible lighting advantages, and the desks can be moved during the day for the best light. Books and other reading matter are printed in large, bold type, and the teacher writes on the blackboard in letters approaching the 20/200 Snellen line. No home work is permitted. The children are kept in the sight-conservation class only for reading and writing and return to their regular classes for other work. There has been much discussion pro and con regarding the value of these classes in conserving sight. The problem as to whether they will prevent progression of

the myopia is as yet unsolved.

Over 4 percent of the new cases seen in the clinics have heterotropia remaining unimproved after refractive errors have been corrected. There is an equal number of cases of amblyopia ex anopsia. Occlusion of the good eye has been advised for years in the latter group, with very unsatisfactory results. During the past two years, enforced patching for five hours daily, in school where it could be observed, has been done. The results, as compared with a control, unpatched group, do not seem promising. There has been no experience with mass orthoptic training. The time element is the greatest problem and obstacle. An attempt is being made to interest the Board of Education to install an instrument for orthoptics in each sight-conservation classroom; the teacher to supervise the training after she has been given instruction as a technician.

Some ophthalmologists believe that the preschool child deserves a complete eye examination. Several attempts have been made to develop screening procedures to select those most in need of care. Recently, play techniques have been developed to secure greater coöperation by the children. At the present time a study is in progress in the eye clinics to evaluate this screening device and its feasibility for widespread use. The coöperation of these young children is amazing. They should be kept apart and noise should be avoided. If one of these children cries, the whole group will cry.

While these methods of mass testing have been satisfactory in general, many children have visual defects which go undetected. Just as we urge the general population to have chest X rays, we should urge them to have complete ophthalmologic examinations, particularly at the preschool age, when the greatest possibility of prevention exists. Pending this

semimillennium, screening methods should be improved by constant review.

Discussion. Dr. Percy Fridenberg said there should be periodic visual tests at higher-age levels. This is of practical importance in giving high-school youngsters useful information on the choice of an occupation for which they are visually fitted and will save them from entering occupational dead-ends. Previous periodic examinations and records become of medicolegal value in compensation cases and civil or criminal suits, giving evidence, for example, that defective vision claimed as a result of injury was present long before such injury was sustained.

Leon H. Ehrlich,
Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

April 16, 1945

DR. SAMUEL J. MEYER, *president*

PRENATAL DETACHMENT OF THE RETINA

Dr. Arlington C. Krause presented a paper on this subject.

CLINICAL MEETING

(Presented by the staff of Children's Memorial Hospital)

ECTOPIA LENTIS

DR. ROY O. RISER reported three cases of ectopia lentis.

Case 1. Dorothy V., aged 11½ years, had been referred to the Clinic a year previously because of poor distance vision. She had been treated medically for chorea, extreme nervousness, and undernourishment. She was wearing an old manifest correction of -0.75D. sph. in each eye, and after atropine refraction was given a new correction: O.D. -6.00D. sph. = +0.50D. cyl. ax. 90°;

O.S. -0.50D. sph. \approx +1.50D. cyl. ax. 90°. Her corrected vision was 20/40 in each eye. She was referred to a sight-saving class.

There was a definite tremor of each iris; the pupils measured 2 mm. in size, and the anterior chambers were deeper inferiorly. After dilation of the pupils (to 5 mm.) a tremor of each lens was visible; each was dislocated up and to the right. The near point of accommodation was 9 cm. in each eye with glasses. She had had occasional pain in the right eye but no increase in the intraocular pressure.

Her father wore a correction for myopia and had a faint tremor of the iris of the left eye. His pupils were not dilated at the time of examination. The daughter had long spidery fingers and feet. She wore size 1AAA shoes, which were so wide on her that she could hardly keep them on. She was referred to the orthopedic clinic for confirmation of the opinion of arachnodactylia, and this diagnosis was confirmed in the patient and in her father by Dr. Compere. This, then, is a case of Marfan's syndrome.

Case 2. Philip H., aged five years, was brought to the Clinic in September, 1944, because one eye turned in occasionally and because of repeated falls. The eyes were found to be parallel. There was a tremor of the iris of the right eye; none was found in the left. Skiascopy under atropine was difficult because of the bilateral dislocation of each lens, up and out, almost to the center of the pupils. The visible margin of each lens was slightly flattened (not notched), and the zonular fibers were easily visible. The fundi were normal. Upon postcycloplegic examination, the following correction was ordered: O.D. -6.00D. sph. \approx +5.00D. cyl. ax. 150°; O.S. -7.00D. sph. \approx +5.00D. cyl. ax. 60°, with which vision O.D. was 20/200, J3; O.S. 18/200, J7.

The patient did not respond well to high plus lenses in an effort to use the aphakic pupil. No heart trouble was found.

The Orthopedic Clinic confirmed the impression of arachnodactylia. This in association with the ectopia lentis becomes a case of Marfan's syndrome. Several members of the patient's maternal family have long spidery fingers and toes, and a few have eye trouble. The boy's grandmother had married a second cousin.

Discussion of hereditary traits and other congenital defects associated with arachnodactylia were omitted because of the excellent material already available in the literature. One point was stressed: whereas Burch states that 50 percent of cases of arachnodactylia will be found to have ectopia lentis, a careful study of the other half will pick up a number of cases of poor or erratic accommodation due to defective zonular fibers or incomplete attempts of the lens to become dislocated.

Case 3. Harry M., aged 5½ years, was seen in February, 1945, because he held objects too close to his eyes. Vision was 20/100 in each eye. There was no iridodonesis. The anterior chambers were slightly shallower above than below. After two refractions under atropine and a postcycloplegic test, the following correction was prescribed: O.D. -4.00D. sph. \approx +6.00D. cyl. ax. 135° -vision 20/70, J7 at 4 in.; O.S. -4.00D. sph. \approx +6.00D. cyl. ax. 75° -vision 20/70, J6 at 4 in.

Cycloplegia permitted a view of the lower edge of each lens. The inferior edge of each lens was slightly flattened (not notched) and the zonular fibers were easily seen. No lens opacities were found, and the fundi were normal.

This patient had no arachnodactylia; his case was therefore considered one of congenital bilateral ectopia lentis. The family history disclosed no evidences of arachnodactylia. The boy had a pigeon-breast deformity not present in other

members of the family. His heart was normal.

SYMPATHETIC OPHTHALMIA

DR. R. C. GAMBLE presented the history of C. T., who suffered a penetrating injury of the left eye in October, 1942, at the age of eight years. It was a serious injury. The eye was very painful, and was therefore enucleated on November 12, 1942. On November 19th the right eye was congested, and on November 28th precipitates were seen on the back of the cornea. The patient was given atropine, typhoid antigen H, and diphtheria antitoxin. When he was first seen by Dr. Gamble on December 16th, the right eye was markedly congested; the pupil was about 3 mm. in size; there were no keratitic precipitates. The aqueous was turbid, but the fundus could be seen fairly well and appeared normal. An adrenalin pack was used at once, and the pupil dilated well. Treatment consisted of sulfathiazole, gr. 60 daily, and atropine, 4 times daily.

By January 16, 1943, the eye was almost white; there were a few keratitic precipitates, and vision was 20/20. On March 1, 1943, the sulfathiazole was reduced to gr. 30 daily, but as the eye again became congested the dose was increased to gr. 60 daily. On June 2, 1943, the sulfathiazole was discontinued. The eye was white, there were a few keratitic precipitates, and the vision was 20/15.

On August 24, 1943, a gray area was noted on the nasal side of the disc and below; this was larger by September 19, 1943, and the eye had been congested. Sulfathiazole was therefore ordered again. At this time vision was 20/50. The fundus lesion slowly became larger and more elevated; by February 28, 1944, it had encircled the disc and spread near the macula, at which point there was a hemorrhage. No other areas of infiltra-

tion were seen and the lens and vitreous remained clear.

By March 13, 1944, vision had dropped to 20/100. At this time 300,000 units of penicillin were given intramuscularly. Possibly there was some decrease in the size of the choroidal infiltration, but it did not vanish.

In May, 1944, the patient had another course of penicillin, with a little more decrease in the size of the fundus lesion, and vision improved to 20/50 by August 28, 1944. This was the last time he was seen, as he was killed in an accident shortly thereafter. The ultimate effect of penicillin in this case could therefore not be determined.

During 17 of the 20 months he was under observation, he was taking from 30 to 60 grains of sulfathiazole or 45 grains of sulfamerazine a day. His red count never dropped below 3,650,000, and the white count varied from 11,300 to 5,200. He gained 14 pounds in weight. Sections of the enucleated eye from the Army Medical Museum showed sympathetic ophthalmia.

MEMBRANOUS CATARACT DUE TO RUBELLA IN THE MOTHER

DR. R. C. GAMBLE said that S. S., aged nine years, had had a normal birth, but there was a cataract in each eye. She also had pyloric obstruction. Her mother had had three-day measles during the first month of pregnancy. At the age of six months, when first seen, the eyes of this child were of normal size. There was a membranous cataract in each eye, with a dense central area and a less dense peripheral area. The pupils reacted to light but dilated poorly with atropine. A faint red reflex could be seen through the peripheral part of each lens. She had no heart disease and was normal mentally.

The lens of the right eye was needled three times; that of the left eye was

needled once. The membranous cataracts were very rubbery and moved about with the knife, making it very difficult to achieve an incision.

The last operation was performed on the right eye, with two Ziegler knives used at the same time. This was more effective than when only one was used.

The vision was R.E. 20/100; L.E. 4/200.

CATARACT DUE TO RUBELLA IN THE MOTHER

DR. W. SEGALL presented two cases of cataract due to rubella in the mother.

Case 1. T. S., a white boy, aged 2½ years, was born in December, 1942, at full term, with a birth weight of 6 pounds. He was the first child of a mother who had had German measles in the first few weeks of pregnancy.

Both eyes were smaller than normal. The corneas measured 8 mm. The pupils were 2.5 mm. in size and did not dilate well under atropine. There were bilateral cataracts. Both eyes were needled, and lens remnants were still present, but a good red reflex was visible in both eyes. The child had congenital heart disease. Neurologic examination gave negative findings.

Case 2. B. W., a white boy, born in November, 1941, at full term, weighed 4 pounds at birth. The mother, who had German measles in early pregnancy, has three other healthy children, two older and one younger than the patient. The child's right eye was smaller than normal. The cornea measured about 8 mm. The pupil reacted to light and dilated fairly well with atropine. There was a complete, fairly gray cataract which has not been operated on. The left eye showed no disease. The child was mentally and neurologically normal; there was no heart disease.

In these cases the findings and histories

were practically diagnostic. The affected eye was smaller than normal; the pupil was narrow and did not dilate well on atropine instillation. The cataract was either membranous or complete. So far the typical lamellar type had not been seen. Surgery was not uniformly successful. The children were underdeveloped as a rule; some had congenital heart disease, some were deaf, some had serious neurologic or mental defects and some showed nevi. There is a possibility that some cases with the same etiology show no eye defects.

As a rule, German measles is a very mild disease, and complications are rare except in epidemics, when a few cases of neural complications have been described (in 1935 and 1943). This may be due to a change in the virulence of the infectious agent. The virus injures the embryonic layers before the placental barrier has been established. The higher the oxygen consumption of the tissue the greater its vulnerability. This applies especially to embryonic tissue and explains the damage to the child and not to the mother.

Among 22 cases of congenital cataract, 4, or about 20 percent, had a history of infection of the mother with German measles in early pregnancy. In a number of cases where the etiology was suspected, the mother could not remember having had the disease. Rubella may sometimes run a very mild course, the rash may be missing, and the disease can easily be overlooked.

The probability seems to be great that such an infection in early pregnancy may result in congenital defects. It is important that the mother be informed of the etiology so that she may understand that subsequent children will not be affected in the same manner.

Robert Von der Heydt.

COLLEGE OF PHYSICIANS OF
PHILADELPHIA

SECTION ON OPHTHALMOLOGY

April 19, 1945

DR. WARREN S. REESE, *Chairman*CONSERVATION OF LID MARGINS DURING
BLEPHAROPLASTY

DR. CHARLES A. RANKIN gave a brief generalization of the care and observation of pre- and postoperative and traumatic cases, with special attention to preserving what might remain of the lid margins. After giving a summary of previous knowledge of successful attempts, he presented the history and treatment of a white boy, aged 17 years, who was treated in the Wills Hospital. The mid-half of the upper lid had been blown and cut away by flying metal in a chemical laboratory explosion. Particles of lid margin were found and reunited by dovetailing. Further and complete lid reconstruction by use of skin and mucous-membrane grafts was made. Final result showed a well-conserved, smooth, even lid margin, with no notching or overcorrection, and cilia well placed.

Discussion. Dr. Edmund B. Spaeth said that many of the truisms which Dr. Rankin mentioned at the beginning of his paper are pertinent. It is as important to know when not to operate further as to know when to operate, and what to do.

Esser, Wiener, Wheeler, and others have written much on the conservation of lid margins in ophthalmic plastic work. Elschnig and Snellen both spoke many years ago of the interposition of dovetailing separate flaps. Dr. Spaeth said that as far as he knew, this presentation by Dr. Rankin is the first instance of separate attention to the lid margin, and to that portion of the lid above the margin. It is a procedure which can be

utilized basically in many traumatic lacerations of the lid.

Dr. James Shipman said that this was a case from which all can learn something. If nothing else, all might be stimulated to teach general hospital internes to stay away from wounds of the eyelids that go through the margin. There is no other surgery performed about the eye by the general hospital interne that causes more harm and leads to more plastic surgery later. Fortunately, this case was seen by someone at the start who realized the seriousness of the condition. Much can be done to prevent the necessity of future plastic surgery by instructing the interne in a general hospital to refrain from sewing up eyelids whose laceration goes through the lid margin.

The lid margin is very delicate and irreplaceable. Sometimes it is difficult to preserve the margin, and obtain good alignment.

ANGIOID STREAKS OBSERVED OVER A PERIOD
OF 36 YEARS

DR. WILLIAM ZENTMAYER said that in a case of angioid streaks which he observed for the first time in 1908 and which he has seen at varying intervals since, the last time in May, 1944, there were in the right eye masses of dense pigment of irregular shapes. In some portions of the fundus there was complete atrophy of the choroid. The gray zone which had formerly been present about the papilla had disappeared, and there was no trace of angioid streaks. The papilla was somewhat waxy in appearance.

In the left eye, the general appearance of the fundus was similar to that of the right eye, except that the areas of complete destruction of the choroid were more extensive and there was a denser massing of pigment. Beneath the superior artery there was a vertical lesion about

three disc diameters in length which had the appearance of the lesions seen in circinate retinitis. The papilla was waxy in appearance.

Vision in each eye was 1/60. The patient had suffered a stroke affecting his speech. The systolic blood pressure was 210 mm. Hg.

The condition of angioid streaks is probably due to degeneration of Bruch's membrane in which tears occur, and the hemorrhages result from similar changes in the walls of the blood vessels; all other fundus changes are a part of the syndrome. The association with pseudoxanthoma elasticum occurs with such frequency that it may be assumed that they have a common origin.

SOME FACTORS IN THE EXAMINATION OF ASTIGMATISM

DR. I. S. TASSMAN remarked that certain difficulties are sometimes encountered which are usually concerned with the accurate determining of the kind and amount of astigmatism, and also the exact determination of the axis of the correcting cylinder. Probably for this reason, a great deal of stress is laid on procedures and tests for making these determinations by subjective examination. The examination and correction of any case of ametropia cannot, however, be reduced simply to a single mathematical or mechanical procedure.

Important factors in the examination of the patient include, first, a proper and thorough analysis and evaluation of the subjective symptoms. Such symptoms include, most commonly, headache, dizziness, double vision, and blurring. Whenever these symptoms are mentioned, it should first be determined whether they are the result of, or associated with, a suspected ametropia, and particularly astigmatism.

Hyperopic astigmatism causes more

discomfort than myopic astigmatism, except when of low degree. The amount of accommodative effort employed is an important factor in the production of symptoms in hyperopic astigmatism. It is also an important factor in dealing with cases of convergent strabismus. In the latter, the deviating eye invariably presents a greater amount of hyperopic astigmatism, usually at an oblique axis; whereas in the fixating eye, very little, if any, astigmatism may be present.

In young children with a fairly high hyperopic astigmatism in one eye and but little, if any, astigmatism in the other eye, amblyopia may occur very early, whether or not a deviation is present. In most cases of astigmatism in young children of early school age, such symptoms and complaints may be absent. In older children and in young and middle-aged adults, subjective symptoms resulting from the presence of hyperopic astigmatism are more common. In very old patients who use the eyes only moderately for close work, a considerable degree of astigmatism may be present without troublesome symptoms. The occupation of the patient also bears an important relationship to the presence of symptoms, the accommodation, and also the type of astigmatism present. Young people who do close work constantly, and who have hyperopic astigmatism which requires the use of a great deal of accommodation will usually complain of headache and ocular fatigue.

A cycloplegic should be employed in determining the refraction of all younger patients. In all cases of astigmatism, whether a cycloplegic is employed or not, retinoscopy should be a routine procedure in providing the basic determination of the refractive error and the axis of astigmatism. The best method for this purpose is what is known as cylinder retinoscopy, at one meter. However,

whether by spherical or cylinder retinoscopy, the preliminary determination by this method should not be neglected. In cases of irregular astigmatism with corneal opacities, scissors motions, immature-lens changes, and other changes in the media, difficulties may be encountered in obtaining an accurate result by retinoscopy. In these cases a closer distance is recommended to obtain the best result possible.

In cycloplegic cases, the subjective test should follow the objective, and in average cases, the results should correspond. In young children the result of a careful retinoscopy is more dependable than the result of a subjective test, and is arrived at in a much shorter time. Postcycloplegic examination should follow the cycloplegic tests. This should provide the final result. Here, the cross-cylinder can be employed in some cases as an auxiliary in checking the axis of the cylinder, and the strength of the combination. The astigmatic dial can also be employed as an auxiliary or preliminary test in some selective patients, but it does not eliminate the need for careful retinoscopy in routine practice.

The result obtained by this method together with a consideration of the age, occupation, and accommodation in particular are the combined factors that should determine the best correction possible for the relief of the symptoms.

Discussion. Dr. Alfred Cowan emphasized what Dr. Tassman had said about the procedure that he followed; that is, the procedure of retinoscopy, known as cylinder retinoscopy. This is probably the most accurate objective test that we know of for persons such as children or others for whose relief we have to depend ab-

solutely on objective tests. This is the only procedure available. It is the only way to determine objectively the amount and the axis of the cylinder.

He agreed with Dr. Tassman with one exception; namely, the importance of the subjective examination. He did not think its importance could be overemphasized. After all, for those persons who can take a subject test, this test is all important. No objective test can be conclusive; no matter how well it is done nor by whom. By means of a subjective test one can probably come closest to determining the exact refraction, a refraction that can be proved; namely, by having the patient read the finest type possible with the best glass.

Dr. I. S. Tassman said that the point he wanted to stress was that he thought there is, today, much emphasis placed on subjective tests while other important factors and the objective examination are more or less neglected. As he stated in his essay, the subjective test provides the final result, but there has been a tendency in the past few years, in the examination of many, to underestimate and neglect the objective tests. He also mentioned such factors as the accommodation, age, occupation, and the nature of the symptoms complained of, as important in properly recognizing the nature of the condition present.

Many different types of people are encountered. There are many who can even lead the examiner astray if he is not careful and depends too much on subjective examination, failing to analyze and properly interpret the replies of the patient.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the Manuscript Editor, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

AN EVALUATION OF ANISEIKONIA AFTER TWELVE YEARS

About 2,500 patients have been examined in the aniseikonic clinic at Washington University in the past 12 years and eikonic corrections have been ordered for some 1,500 of them. Many of them have been examined ophthalmologically by the writer. So many, in fact, that scarcely a week now passes without at least one returning to report and be rechecked. The writer believes that he is now able to evaluate fairly well this type of examina-

tion, and this article gives his impressions.

That aniseikonia is not an unusual condition seems to be generally accepted, though there is still the occasional commentator who thinks that phorias and not size differences are being recorded in the measurements of aniseikonia. This point of view seems to have lost ground in the last few years, and for purposes of this discussion the fact that aniseikonia exists as such and is measurable with reasonable accuracy and that lenses to correct this, as well as other errors of re-

fraction, can be readily made is a premise in this article.

On two occasions questionnaires have been sent by the writer to patients for whom eikonic glasses have been ordered. In each case, over 100 replies were received. In the first series, no particular attention was paid to the time elapsed between sending the questionnaire and the eikonic examination but, in the second, at least a year had passed. These reports have been published previously. They varied little and are strikingly similar to those from Dartmouth and New York sources. They indicated that approximately 80 percent of patients were moderately helped by the corrections and 50 percent completely relieved of their symptoms.

However, statistics can be interpreted almost as one wishes, and it is my impression that these results are far better than can be attributed to the aniseikonic correction alone. How then are we to account for the benefit undoubtedly obtained?

The primary impression that the examiner has of the patients who have come for the examination through the years is that most of them are neurasthenics. Few come from the local community of even as large a city as Saint Louis; probably not more than 5 percent. What does this mean? Primarily it is apparent that these people have not found satisfaction from the routine refraction available locally to them. Many have consulted a half-dozen ophthalmologists and optometrists and have found no examiner who has had the time, interest, or the necessary qualifications to make a psychiatric study of their cases. Finally, in desperation, some ophthalmologist thinks of aniseikonia and says to himself, "Oh, *there* is something that I haven't tried. Let's send him—or often her—to an aniseikonic clinic. If it doesn't accomplish anything else, it will rid me of this difficult patient for a while,

so I'll pass him on to someone else." Truly aniseikonia is the waste basket of ophthalmology.

One may ask how these neuroses have seized on these patients. Sometimes it originates from over-anxious parents, often from thoughtless eye examiners. I quote from Mary Jane Ward's current best seller, "The Snake Pit" in which the memory of the inmate of the asylum concerning the first visit of an oculist is thus stated: " 'Is there any danger of her losing her sight?' mother asked the doctor. You were ten then. 'Well', said the old coot of a doctor, 'Well,—I don't—think so!' For years you felt as though you were committing a crime if you read anything that was not required. And reading was the only thing you cared much for."

In such a way was this particular child prepared to look for eye troubles all her life. She was, as are many others of unstable nervous systems, made the victim of ill-advised suggestion. A large percentage of the aniseikonic patients we see belong in this neurotic group. Only a little ocular discomfort, burning, smarting, or headache is necessary to convert them into ocular neurasthenics. Every illness, every failure is laid to their eyes. No wonder, if they happen also to be nervously unstable, it is difficult to satisfy them with the usual, and often hasty, ocular examination.

In the group of those helped are those with whom the ophthalmologist versed in psychiatry has taken time to talk over their cases most carefully and has often been able to point out their neurotic tendencies and show them that much of their disability is of their own making. Such a conference may be a good start toward cure, and, when added to it is a correction for aniseikonia that may be quite minor and no part of their trouble which, however, has been arrived at after

a long trip by the patient and an impressive examination after arrival, these people often get relief. Many of us have more aniseikonia than some of these patients and nevertheless experience no trouble from it, just as small plus spheres may be necessary for some when a like correction is entirely superfluous for others. Many of these patients can later discard the eikonic lenses after making the mental adjustment necessary to comfort. This group is by far the largest of the 80 percent who attain some relief from eikonic corrections. It is composed mostly of those who have taken the smaller corrections. Among them are those whose tests for refraction have been poorly made; perchance, an astigmatic axis badly placed or a hyperphoria overlooked. If such patients do not come from too far away, it has been our practice to return them to the referring doctor with a tactful note and no eikonic correction given. Such would be the usual procedure if the patient had obvious muscle weaknesses that had never been considered or if he had neglected sinusitis. However, many of these conditions are borderline, and eikonic tests are made, and if aniseikonia is found and the patient comes from afar, the prescription is given, but the patient is advised about orthoptics or to have examination of the sinuses. The treatment of any of these pathologic conditions instead of the correction for aniseikonia may be responsible for the relief.

In the last and, I believe, the smallest group, aniseikonia is the only abnormality and is responsible for the symptoms. In general, these patients have the largest amounts of aniseikonia, and those in this group are the most dependent on their corrections. I believe that most of such patients are really optically helped. Often, very often in fact, they are also somewhat neurotic, but their neuroses have the organic basis of aniseikonia, and relieving

this not infrequently cures the neuroses.

From the foregoing analysis, one cannot escape the conclusion that most of those supposed to be helped by eikonic glasses are really helped by something other than these. If this is correct, we must ask the following questions. Should aniseikonia become a routine office practice, should there only be stations in the large centers for such studies, or should eikonic tests be relegated to the limbo of matters better forgotten?

In my opinion, the second course is the best. The cases dependent solely on this correction for comfort are too few to justify its measurement in the doctor's office. It takes too much time, energy, and expense, and the ophthalmologist cannot afford to do it. I discard the idea of total abandonment of the tests because it would be unfair to the small group whose comfort depends on this correction. Hence, I advocate the idea of having a few central stations for these tests. Great care must be taken in their selections, as certain requirements are necessary. First and foremost, there must be a well-trained, especially psychiatrically trained, conscientious ophthalmologist who has ample time for the study of the patient or, in lieu of this, a competent ophthalmologist with a consultant in psychiatry. There should also be a rhinologist available. If the eye physician is not an eikonic technician, obviously one must be supplied. Several days should be allowed for the first examination because here, if ever, a thorough study of the patient is needed. This plan may be medically sound, but is it practical? How can all this be financed? Certainly it will be expensive, but there may be enough wealthy patients to pay for the aniseikonic patients who are poor, since, fortunately, there are fewer neurotics proportionately among the poor; they haven't time for neuroses.

Another precaution is necessary. Treatments that are wrapped up in the care of neurotics may readily become "rackets," and the examination for aniseikonia may fall easily into this class. Hence, only by the use of rare judgment and scrupulous honesty can these patients be wisely handled.

Lawrence T. Post.

A PLEA FOR BETTER INSTRUCTION IN PERIMETRY

In recent months a good deal has been said about the importance of basic sciences in the practice of ophthalmology, and emphasis has been laid upon the necessity of making available the proper instruction in these subjects. At a recent examination held by the American Board of Ophthalmology this need was further emphasized by the appalling number of candidates who failed in perimetry.

There can be little doubt of the diagnostic value of defects of the visual fields. In the diagnosis of prechiasmal and chiasmal lesions, as well as in lesions affecting the optic tract and radiations, the visual fields are of immense diagnostic value to the internist and the neurologist.

In addition to peripheral-field studies as charted with the perimeter, the study of the central fields of vision as carried out on the tangent screen is most important in the proper diagnosis of a number of important diseases. Often the course of the disease can be determined only on the tangent screen.

In the various types of prechiasmal optic-nerve lesions, such as optic neuritis and retrobulbar neuritis, the central fields explain the diminution or loss of central vision and often make the diagnosis.

In chronic glaucoma, perimetry is of the greatest importance. It is the only means by which the degree of damage can be determined in the early stages of

the disease and is the only method by which the course of the disease may be followed and the treatment evaluated. As is well known, the early field changes are nerve-fiber-bundle defects producing characteristic defects in the central 20 degrees of the field. The tangent field is the most delicate of the perimetric methods and will detect the earliest changes. These defects develop into the various scotomata such as the Seidel scotoma, the Bjerrum scotoma, or Rønne's nasal step, all being merely manifestations of a nerve-fiber-bundle defect or so-called arcuate scotomas. That there may be many variations is self-evident to one familiar with the cause behind the production of these defects.

Even earlier than the scotomas there may be general depression in the field of vision as determined by small visual angles. The depression may not be constant in the very early cases. The initial rise of tension is usually transitory, so that defects disappear when the tension is lowered. This depression may precede, accompany, or follow the appearance of the scotomas. In angioscotometry the earliest sign is a slight enlargement of the vessel shadows with enlargement of the blind spot.

The ophthalmoscopic diagnosis of the early glaucomatous cup may not be easy. The tension varies during the day, and, when seen, the patient may have a normal tension even though early field changes are present. In addition, a large physiologic cup, a senile cup, a myopic disc, and certain types of congenital anomalies of the disc such as staphyloma verum peripapillare or a congenital excavation, may all suggest glaucoma. Often it is the very carefully done perimetric field studies that make the final diagnosis.

From what has been said it is self-evident that the ophthalmologist must not only have a thorough knowledge of the

neuroanatomy of the eye but must also understand thoroughly the course of the nerve fibers in the retina. In addition, the ophthalmologist must have charted enough fields to have learned the pitfalls to avoid in this examination and must never forget that it is a subjective examination. He must also have done sufficient perimetry to learn to appreciate the many variations that may occur in the diseases that produce field changes. A great deal can be learned from the standard books on the subject, but it requires the supervision of a teacher to see that the proper technique is learned. Left to his own devices the student may develop habits that distort and render inaccurate his findings.

In the recent American Board of Ophthalmology examination it was apparent that most of the candidates did not know their neuroanatomy and therefore had difficulty in locating cerebral lesions from perimetric field defects. Many of them had a very hazy idea of the course of the nerve fibers on the retina and were unable to demonstrate the course of the field changes in a nerve-fiber-bundle lesion. Depression of the field of vision was an unheard-of term to some of the candidates. In addition, questioning elicited the information that many of the candidates had actually made very few field studies. It must be admitted that the taking of a visual field often is a difficult and tedious task, and yet that field may be an important link in the diagnosis of a condition of grave concern to the patient. Therefore, if the field is to be of any value it must not only be properly taken, it must also be properly interpreted. In order to do this it is necessary that the student have the theoretical knowledge supported by sufficient experience in perimetry to enable him properly to interpret the patient's reactions in the process of obtaining that field.

The fault is not entirely that of the

student. In too many institutions the taking of the fields is left to a technician who looks upon it merely as a "job" and is not interested in teaching the resident the proper methods to be employed. It is essential that the men responsible for the training of ophthalmologists realize their responsibility in the instruction in this method of examination. It must be admitted that during the war the doctors were so overworked that in many places it became necessary to neglect the teaching of what residents the institution had. Perhaps this accounts for the glaring defect in training noted in the recent examination. It is earnestly hoped that the proper teaching of perimetry will receive the attention it so justly deserves in the development of the "safe ophthalmologist."

Frederick C. Cordes.

THE EYE BANK FOR SIGHT RESTORATION, INC.

After a year of difficulties, and achievement in spite of these, the Eye Bank has become firmly established and is fulfilling its most important function. This is the collection and distribution of eyes, the corneas of which are to be used as material for the transplantation operation. It makes little difference if the demand for these corneas is small, or that the cases that are suitable for the operation are not numerous, or that the ophthalmic surgeons who are competent to perform the operation are few. There is no question about the need for this service. In these days of crowded hospitals and administrative difficulties, the problem of getting the recipient patient ready and the donor cornea at hand, at one and the same time, would have been one perhaps impossible of solution. This problem, however, is now solved, for all that one needs to do is to get in touch with the

Eye Bank and an eye, sterile and preserved, is immediately shipped by air or messenger within a relatively few hours.

In the past the surgeon has had to wait until he had a suitable donor lined up, or material from a still birth available when needed. When the operation was performed by less than a handful of pioneers (who deserve and receive great credit for their contributions) working in very large communities, this problem was not too difficult. Now, however, more and more ophthalmic surgeons are competent to do this type of surgery, and many more are becoming trained in its meticulous though relatively simple technique. It is therefore becoming increasingly unnecessary for patients to travel great distances, at considerable expense, in order to have the operation performed. The donor's cornea is made available as near to the patient's domicile as possible.

The planning and management of this successful venture into a new and dramatic field of service have required great foresight and skill. Some opposition to the idea was expected and encountered, but gradually this has subsided, and now the venture is met on most sides by good will and active participation. The promoters of the idea would prefer to remain in the background and let the scheme speak eloquently for itself. But it is only right to let those interested know that the plan was conceived by Dr. R. Townley Paton and ably promoted and executed by Mrs. Breckinridge, the executive-director of the Eye Bank, both of New York. The American Red Cross and the airlines loyally contribute their services without which the plan would collapse.

The legal incorporation of the Eye Bank for Sight Restoration in the State of New York tidies up the matter in a most efficient fashion. The Certificate of Incorporation, filed February 21, 1945, includes, among many important stipula-

tions having to do with the main function of the Corporation, several paragraphs of great interest and importance. Two of these are quoted here:

"To carry on, directly or indirectly, such research, experimentation, etc., as may be reasonably calculated to be of value in saving, restoring, aiding or preserving eyesight or in helping to prevent or avoid blindness or impairment of vision of any sort or to ameliorate the condition of the blind or those with defective eyesight; to maintain laboratories, clearing houses of information and the like for this purpose. . . . To aid, freely and voluntarily, in any manner which may be permitted by law, by loan, guaranty, grant, scholarship, fellowship, subsidy or otherwise, any corporation or association or any surgeon, physician, scientist or student engaged in saving, restoring, aiding, helping to prevent or avoid blindness, or in whose work or welfare the corporation may have any other lawful interest. . . ."

Thus it is the purpose of the Eye Bank for Sight Restoration, Incorporated, not only to take care of the supply and distribution of corneas but to go further and train young surgeons in the technique of the operation as well as to encourage research studies in the sources, preservation, and handling of the material by laboratories or research workers anywhere.

To carry out this great purpose funds are, of course, needed. The public response to this stimulating and dramatic cause has been, and continues to be, strong and active. As more funds become available, the influences set afoot by the work of the Eye Bank are certain to spread and result in much good to the cause of human welfare.

The training of ophthalmic surgeons is one of the most vital needs of this or any other country. Much has been done in

the past by individuals, and there are many fine organizations successfully engaged in this humanitarian purpose. The developing of skilled, resourceful, and competently trained ophthalmic surgeons has been somewhat casual and restricted. There are too many ophthalmologists doing eye surgery who are not topflight, and patients' eyes have been lost that otherwise, in abler hands, might have been saved. This indictment is less severe now than a few years ago, but there is still much room for improvement. Thus any agency that has for one of its purposes that of training ophthalmic surgeons in further skills should be welcomed, appreciated, and supported. It is time that the attention of the public be directed to the possibility of preventing many cases of blindness through the development and training of competent surgeons, rather than that it be content with supporting the worthy agencies that devote themselves to the care of the patient after blindness becomes an established fact.

Thus it is gratifying to see elsewhere in this issue the announcement of the award by the Eye Bank of seven scholarships to ophthalmologists for training in the technique of the corneal-grafting operation. It means that seven more American ophthalmologists, from various parts of the country, will be trained in further surgical skills.

Regional Branches are needed to complement or augment the work of the National Eye Bank. Such a branch has recently been established in Chicago to serve the Mid West. It is under the direct control of the Chicago Ophthalmological Society through a board of governors composed of the heads of the Departments of Ophthalmology of Northwestern, Illinois, Chicago, and Loyola Universities, and the directors of the eye departments of the Illinois Eye and Ear

Infirmity and Cook County Hospital, all of whom are members of the Society. The branch is physically established in Cook County and is about to function. It receives and distributes eyes from and to hospitals and surgeons in the midwestern area through affiliated groups of hospitals and ophthalmological societies. Surplus material that is not used within 12 to 24 hours is forwarded to New York. Calls on Chicago that cannot be satisfied are referred to New York. Eyes that cannot be used, as well as those the corneas of which have been utilized, are either returned to the sender or kept for microscopic study and report.

The Branch enjoys the support and the legal backing of the Eye Bank itself and in return takes an active part in its great humanitarian purpose. Controlled as it is by the prestige and ethical standing of its board of governors, the Chicago Branch is in a position to control publicity that otherwise can be spectacular, harmful, and unethical, can see to it that the material is wisely dispensed, and is in a strong position to judge the merits of applications for scholarships, fellowships, and so on that may arise within its sphere of influence. As the first Branch to be founded, and because of its high principles, it will serve as a guide to the establishment of further branches in other sections of the country.

It is not the purpose of this editorial to give exact and detailed information regarding the techniques of the Eye Bank. Requests for such information should be directed to the Eye Bank for Sight Restoration, Inc., 210 East 64th Street, New York. Hospitals and the members of local ophthalmological societies are urged to become affiliated with this movement so that more surgeons can obtain more material to make more blind to see.

Derrick Vail.

BOOK NOTICES

OPHTHALMIA . NEONATORUM.

THE PROBLEM AFTER THIRTY YEARS OF STATUTORY NOTIFICATION AND SIXTY YEARS OF CREDE' PROPHYLAXIS. Monograph No. 1 of the Institute of Ophthalmology. By Arnold Sorsby. Paper covers, 65 pages. 10 figures, 15 tables, index. London, published by Hamish Hamilton Ltd., 1945. Price not given.

Sir Allen Daley, Medical Officer of Health, County of London, in his foreword to this excellent monograph, compliments the author for "bringing up to date all the available knowledge, statistical and clinical," concerning the subject. His statement that "the monograph will be invaluable to ophthalmic surgeons, obstetricians, midwives and public health workers" is indeed not open to question.

The author has succeeded in condensing within a relatively few pages a subject that is difficult to handle from a statistical viewpoint. Likewise, it is not easy to discuss succinctly the modern aspects of the prevention, prophylaxis, and treatment of ophthalmia neonatorum within a limited space. Those who are familiar with Sorsby's writings recognize his ability to compress much important information without losing continuity, and this monograph is no exception.

One will find within its pages evidence that while the complications of ophthalmia neonatorum are being rapidly eradicated, the incidence of the disease itself, at least in Great Britain, is no less frequent today than it was possibly 40 years ago. The common organisms, as well as the gonococcus, causing the disease rapidly respond to modern chemo- and, more recently, penicillin therapy, often within a matter of a few hours in the latter event. The widespread beliefs that ophthalmia neonatorum is practically synonymous

with gonococcal ophthalmia and that reliance therefore can be placed on the disinfection of the newborn baby's conjunctival sac are, according to Sorsby, responsible for the fact that ophthalmia neonatorum is not less frequent now than before the newer agents of treatment were discovered. These fallacies should be uprooted. The disease in the mother during pregnancy has been neglected by obstetricians, and Credé's method of prophylaxis, valuable as it is, has been forced in the past, at any rate, to carry more of a burden than it is capable of doing. There remains much to be learned and much to do before this blinding disease is completely eradicated.

If the monograph succeeds in causing us to stop and look and evaluate, it will have done its good work; and medical smugness over the value of the Credé method is due for a fall.

It is hoped that monograph No. 1 is but the beginning of a long line of similarly excellent and noteworthy monographs that we have a right to expect from the newly founded British Institute of Ophthalmology. All ophthalmologists will wish it success and hasten to extend their sincere congratulations to the Institute for its bright future.

Derrick Vail.

A BIBLIOGRAPHY OF VISUAL LITERATURE, 1939-1944. Compiled by John F. Fulton, Phebe M. Hoff, and Henrietta T. Perkins. Clothbound, 117 pages. Springfield, Illinois, Charles C Thomas, 1945. Price \$3.00.

This work is a wartime project produced under the aegis of the Committee on Aviation Medicine, Division of Medical Sciences, National Research Council, acting for the Committee on Medical Re-

search of the OSRD. It is also listed as Publication No. 11, Historical Library of the Yale Medical Library, the work having been done under a contract between OSRD and Yale University.

Articles and books are listed to the number of 3,537 in the standard form by author, with title of paper (or book), name of journal (abbrev.), year, volume number, and page numbers. The classification comprises nine principal group divisions as follows: Anatomy and Ophthalmology, Physiology and Psychology, Visual Examination and Testing (including Methods and Instruments), Correction of Ocular Defects in Military Personnel, Training for Military Specialties (including Optimal Conditions and Procedures, Job Analyses), Ocular Trauma (in Military Services), Goggles and Ocular Protection, Illumination, Visibility. In each of these divisions there are from two to twenty subdivisions, and under many of these are secondary and other subdivisions. The above classification is admittedly arbitrary, but is primarily based on presumed military usefulness. It was devised with the collaboration of a number of eminent high-ranking American and British staff officers, among whom the aviation branches are well represented, and whose names and connections are stated in the Preface.

This bibliography was compiled essentially for military purposes, and accordingly makes no claim to completeness. The effort has been concentrated on the biologic phases, with special emphasis on the literature of psychology, and to the exclusion of aerial photography, optical engineering, and optometry, and, to a large extent, of general ophthalmology and ocular pathology. Notwithstanding all this, there is much material listed in several of the divisions which will be of decided interest and value to the civilian ophthalmologist. The authors are to be

commended for the excellence of their work.

William F. Moncreiff.

JOURNAL OF THE HISTORY OF MEDICINE AND ALLIED SCIENCES. January, 1946, Volume Number 1. George Rosen, editor. Published quarterly by Henry Schuman, New York. Subscription rates, \$7.50 a year in the United States, Canada, and Latin America; \$8.50 in other countries.

If the first number of the *Journal of the History of Medicine* is any indication, the future success of this venture is assured. It is beautifully printed on paper of excellent quality, illustrated profusely with portraits and facsimiles that capture the spirit of former times, and is a credit to the printer's art. The body of the *Journal* thus has great charm. Its contents, however, are what count, and the editor has succeeded in getting together for this, his first issue, 10 outstanding articles of interest to all physicians regardless of their specialties. Subsequent issues are promised that will continue the high quality and variety.

In his introduction the editor points out that he does not want to cultivate medical history as a mere search for antiquities, as a kind of hunt for curios, but rather as a vital, integral part of medicine. He states that he "will not stress the technical aspects of medical history, but will endeavor, while maintaining the highest literary and scholarly standards, to present studies that can be of interest to as large a section of the medical profession as possible."

Those who are interested in the culture of Medicine, and there is every reason to believe that these are not few in number, both here and abroad, will welcome this new *Journal* and wish it success.

Derrick Vail.

OBITUARY

MAX POSER

1870-1946

Dr. Max Poser, special technical representative of Bausch and Lomb Optical Company, died at his home in Rochester, New York, on January 4, 1946. He was born on November 8, 1870, in Jena, Germany. His formal education, under the guidance of Dr. Ernst Abbé, was obtained in the University of Jena, from which he was graduated with the degree of Doctor of Physiological Optics, in March, 1889. He became affiliated with the London Branch of Bausch and Lomb on August 1, 1913, and came to Rochester a year later.

Many years of Dr. Poser's colorful life were spent in consulting with, and assisting, leaders in scientific endeavor. He was considered one of the world's greatest microscopists. The solution to such problems as the control of infection in surgery, malaria, and sleeping sickness received valuable aid from his vast knowledge of optical principles and instruments. His keen insight into the problems of vision contributed to the design of many of the eye-examination instruments, such as the Ives Acuity Apparatus, Stereo Campimeter, and the Poser Slitlamp which are in general use today.

In his later years, Dr. Poser spent most of his time in photomicrography, assisting research professors throughout the United States.

In 1937 he was made a Life Technical Advisor of the American Academy of Ophthalmology and Otolaryngology. He was a member of many scientific societies, including the Royal Institution of Great Britain, British Physical Society, Royal Photographic Society, and held a Fellowship in the Royal Microscopical Society. He was a member of both the Optical Society of Great Britain and America, the American Association for the Advance-

ment of Science, Pan-American Congress of Ophthalmology, American and New York State Optometric Associations, National Society for Prevention of Blind-

ment, and the Franklin Institute. He was an honorary member of Beta Sigma Kappa, serving on the scientific section of the Advisory Board of Research.

The personal and gracious charm of Dr. Poser contributed in no small measure to his popularity with ophthalmologists, among whom he had many friends and admirers. He was such an intimate part of the Bausch and Lomb exhibits at all of the conventions of the ophthalmological societies that it will be difficult to imagine the meetings without him. He was always eager to explain most minutely and patiently the ingenious intricacies of the many scientific optical instruments displayed. He was a master of all of them and a designer of many. The younger men particularly looked on him as a teacher of power and ability. His loss will be felt keenly.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the *Ophthalmic Year Book*. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the *Journal*.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |

GENERAL METHODS OF DIAGNOSIS

Benton, A. L. A visual retention test for clinical use. *Arch. Neurology and Psychiatry*, 1945, v. 54, Sept., p. 212.

A brief test of visual retentive capacity, available in two equivalent forms, has been developed for use in the mental examinations of patients as a supplement to the auditory-vocal digit-span test.

The test involves sensorimotor components which are different from those involved in performance on the digit-span test; the material to be retained is of a nonsymbolic nature, and performance on the test is relatively insensitive to emotional and tensional influences.

The normative data indicate a close relationship between the visual-retention-test score and the level of general intelligence.

Investigation of the performance of patients with cerebral lesions indicates that the test is of value in defining the scope and severity of intellectual impairment.

Normative scores have been developed on the basis of the standardization data, and a manual of directions for administration and interpretation of the test has been developed.

Theodore M. Shapira.

Bulnes, L. S. The participation of the ophthalmologist in carnio-encephalic injuries. *Arch. de la Asoc. para evitar la Ceguera en Mexico*, 1945, v. 3, p. 31.

The author describes the ocular symptoms common to all head injuries, principally the pupillary changes, papillary edema, and variations in blood pressure in the central artery of the retina, "the magnificent and early sign of intracranial hypertension."

For purposes of further description the author divides the cranium into anterior, middle, and posterior segments, and further subdivides each of them into floor and vault. A comprehensive list of ocular symptoms of great diagnostic value is presented under these divisions.

Jerome B. Thomas.

Epstein, E., and Lesser, S. A. H. A trick test to detect night-blindness "malingerers." *Brit. Med. Jour.*, 1945, Nov. 10, p. 644.

Malingers who claim nightblindness can be detected by determining with the adaptometer the minimal intensity at which red light can be seen. Even if the periphery of the retina is diseased there should be no increase in the minimal intensity at which red light is visible with the cones of the normal macula. If the subject affirms that he sees the red light only when it is bright, he is trapped as a malingerer. This observation has been confirmed in patients who have retinitis pigmentosa, diffuse chorioretinitis, and advanced glaucoma with good macular vision. Severe nutritional deficiency in which the central vision is reduced by vitamin-A deficiency might be the only exception.

R. Grunfeld.

2

THERAPEUTICS AND OPERATIONS

Báthori, Z. Nicotinic acid in ophthalmology. *Klin. M. f. Augenh.*, 1942, v. 108, Nov.-Dec., p. 725.

When nicotinic acid is given intravenously or intramuscularly it causes dilatation of capillaries and precapillaries with reddening of the skin. At the same time it lowers the systolic and diastolic blood pressure. Báthori observed that nicotinic acid also produces a dilatation of the retinal vessels and conveys a better blood supply to the retina and choroid. Five to 10 minutes after injection of at least 50 mg. the vision of patients suffering from pigment degeneration of the retina and from choroiditis improved markedly and the visual field expanded extensively. Nicotinic acid was also used in cases of quinine amblyopia, arterio-

sclerotic retinal disease, and senile macular degeneration. It was usually given in combination with vitamin B₁. In cases of retinitis pigmentosa, choroiditis, retrobulbar neuritis, and angiospasm its effect was often striking. Choroiditis Förster, syphilitic optic atrophy and vernal conjunctivitis were not improved by nicotinic-acid therapy. (17 vision fields.) F. Nelson.

Chamlin, Max. Effect of talc in ocular surgery. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 369-373.

Since rubber gloves have become popular in the operating rooms of many ophthalmic institutions, one is prompted to study the effect on the ocular tissues of the talc powder on these gloves. The talc used in the present study was obtained from the Chas. B. Crystal Co., Inc., who furnished the following quantitative analysis: Silica (magnesium trisilicate), 60.04 percent; aluminum oxide, 1.80 percent; iron oxide, 0.16 percent; calcium oxide, 0.38 percent; magnesium oxide, 30.98 percent; loss on ignition, 6.22 percent.

One series of studies consisted of the withdrawal of varying amounts of aqueous from rabbit eyes and the replacement with similar amounts of suspension of talc of varying concentration in an isotonic solution of sodium chloride. The second series consisted of iridectomies, with irrigation of the anterior chamber with a suspension of talc which was injected between the extraocular muscles and the sclera.

The author demonstrates that talc produces granulomas in the eyes of rabbits. When rubber gloves are used, it is advisable to remove all the talc before operating.

In the recent literature, there has

been a good deal of discussion on substitutes for talc. The two substances most favorably received thus far are potassium bitartrate and hydrolyzed starch.

Before the new powder is adopted for use in surgical procedures, however, it would be well to carry out studies similar to those described with talc.

R. W. Danielson.

Deloge, D. Visual reëducation. *Ophthalmologica*, 1943, v. 105, Feb., pp. 91-105.

The author describes Remy's diploscope. He discusses the advantages of the apparatus and demonstrates why it improves orthoptic training and why it helps to a better understanding of the physiology of vision.

The author, who has worked on visual reëducation since 1905, favors Remy's diploscope because it permits a reduction of the phenomena of the visual process. Furthermore, it makes binocular vision possible in patients who otherwise could not be either improved or cured.

A detailed discussion of the treatment of high anisometropias and aniseikonias is given. The vision in an amblyopic eye improves more rapidly than with monocular occlusion. He also mentions his remarkable success in the treatment of any kind of squint. (1 figure, references.)

Alice R. Deutsch.

Dubois-Poulsen. Penicillin in ophthalmology. *Ann. d'Ocul.*, 1945, v. 178, March, pp. 82-100.

Penicillin is bacteriostatic but can be bacteriocidal and bacteriolytic, and is most active during the invasion stage while bacteria are multiplying. In ophthalmology, its greatest usefulness is in infections due to staphylococci,

hemolytic streptococci, pneumococci, meningococci, gonococci, and *Spirochaeta pallida*. In staphylococcal infections it is twice as effective as the sulphonamides. Resistance to penicillin is less frequent and more slowly acquired than to sulphonamides. Affections of the posterior segment of the eye are best treated by intramuscular or intravenous administration. The former acts more slowly but is retained in the tissues longer. The latter is eliminated in 30 minutes except for 10 percent, which is eliminated within three to four hours. Generally speaking, instillation is used for conjunctivitis, ointments for blepharitis and subconjunctival injection for corneal infections. The solution used for instillation every one to two hours has 1,000 units per 1 c.c. in an isotonic saline solution, pH 7.7, with or without wetting agents such as aerosol. The ointment used has 250 units per 1 c.c. in a base of 25-percent vaseline, and 75-percent cold cream. For subconjunctival injection 1-2 c.c. of solution containing 2,500-5,000 units per c.c. with 2-percent novocaine is used. The last is the most effective. For use in the anterior chamber, 0.4 c.c. aqueous is removed and replaced by a solution containing 500-1,000 units per 1 c.c. Numerous illustrative cases are presented.

Charles A. Bahn.

Jensen, V. A. The use of jod-plaston for testing cataract knives. *Acta Opth.*, 1943, v. 20, pt. 1, pp. 95-96.

Unable to secure chamois skin, the author found a suitable substitute in jod-plaston, a catgut-like animal membrane used for interposition between surfaces in surgery. Ray K. Daily.

Kekcheev, K. K. Methods of accelerating dark adaptation and improv-

ing night vision. War Medicine, 1945, v. 8, Oct., p. 209.

In order to accelerate dark adaptation of the eyes of pursuit pilots the following methods were found useful: The pilot can be housed in moderately illuminated buildings; he must avoid bright light. Wearing goggles with light filters all day long is impracticable under combat conditions because it causes fatigue. The sensitivity of the dark-adapted eye can be increased five to six times if it is exposed to red light. The pilot may use the short period while he is waiting in the cabin of his airplane before his motors are started, to expose his eyes to red light of definite brightness which is turned off immediately before taking off. The instrument panel should be illuminated with weak red light.

The functional capacity of the dark-adapted eye can be increased by direct action on the cortex of the brain by means of pharmacologic substances, such as caffeine. Caffeine increases the minimal-brightness perception, the contrast sensitivity, and the depth perception and lowers the threshold of differentiation. The caffeine effect appears half an hour after the drug is given and lasts for $1\frac{1}{2}$ hours.

Weak and brief excitations of any sense organ—such as, sounds of low intensity, low concentration of gustatory and olfactory stimulants, or light muscular work—raise the sensitivity of the dark-adapted eye, whereas strong, and prolonged stimulation usually lower its sensitivity. Simultaneous action of two excitants combine their effect on night vision. Gustatory stimulants (sugar, table salt, and organic acids) or olfactory stimulants (geraniol and oil of bergamot) in definite dosages, increase the sensitivity of the dark-adapted eye.

Diminution of visual acuity and color vision at high altitude is caused by anoxemia and can be combated by the administration of oxygen. Up to the level of 3,000 feet the anoxemia can be relieved by the intake of relatively large doses of dextrose.

Leinfelder, P. J. and Paul, W. D. Oral penicillin in ocular inflammation. Amer. Jour. Ophth., 1946, v. 29, April, pp. 450-451. (1 table, references.)

Lijó Pavia, J., and Lachman, R. Penicillin and metastatic endophthalmitis. Rev. Oto-Neuro-Oft., 1945, v. 20, March-April-May, pp. 29-34.

The authors quote Chester S. Keefer's list of diseases amenable to penicillin therapy, especially the sulfar-resistant conditions. In ophthalmology, penicillin is of great help in such conditions as acute and chronic blepharitis, acute conjunctivitis, infected corneal ulcers, dacryocystitis, hordeolum, and recurrent chalazion and prophylactically after injuries. A collyrium of 250 to 500 units per cubic centimeter, and an ointment containing 30-100 units per gram, are employed topically. There is minimal local reaction to the drug and vehicle. For endocular and retrobulbar infections the drug is administered intravenously.

A middle-aged diabetic patient with cachexia and pulmonary disease is described, who developed sudden blindness of the right eye due to uveitis with hypopyon. Sulfonamide therapy was instituted and atropine was instilled. A characteristic endogenous endophthalmitis with a typical vitreous abscess supervened. Penicillin was given and after two days the eye was considerably improved. After 400,000 units had been administered the inflamma-

tion had subsided but the pupil remained secluded. The authors conclude that penicillin therapy should be instituted at the first sign of severe intra-ocular infection. (References.)

Edward Saskin.

Parry, T. G. W., Laszlo, G. C., and Penistan, J. L. *Penicillin in ophthalmology*. *Brit. Jour. Ophth.*, 1945, v. 29, Sept., pp. 479-485.

The experiences of the authors in the use of penicillin in a country hospital are presented.

Solutions of more than 100 units per cubic centimeter retained their potency for many weeks in the refrigerator and for at least a fortnight at room temperature.

Solutions were applied as follows:

(a) In acute conjunctivitis with secondary corneal ulcers, instillations of penicillin (250-500 units per cubic centimeter) into the conjunctival sac were made every two hours during the day and night for 72 hours and after this period, during the day only. Signs of improvement were observed after two or three days with complete cure in five to seven days.

(b) In four cases of serpent ulcer of the cornea instillations of a solution of 1,000 units per cubic centimeter were made into the conjunctival sac. The solution was instilled every two hours during the day and night for five or six days and then continued in the daytime only. The treatment was combined with irrigation of the lacrimal passages with a solution of 250 units per cubic centimeter twice daily. Cure was obtained in 10 to 14 days. Hypopyon was present in all cases.

Two cases of gonococcal ophthalmia were treated in a similar manner. All discharge of pus ceased in three days, and complete cure ensued in one week.

There was no corneal involvement in either case.

(c) A concentrated solution of penicillin was used in a case of penetrating wound of the sclera before it was sutured. The wound healed in five days without any evidence of infection; but a low-grade iritis supervened, and the eye was removed, owing to the risk of sympathetic ophthalmia.

Two cases of endophthalmitis, one, a part of a pneumococcal pyemia and the other a perforating injury previously treated outside the hospital, were treated with penicillin solution. In the first case, that of a patient aged 78 years, 10,000 units per cubic centimeter were applied to the anterior chamber through a keratome incision on two successive days. Then systemic penicillin was used; but hypostatic pneumonia developed, and the patient died. The eyeball was full of pus.

The second patient had three applications of 20,000 units per cubic centimeter of penicillin installed into the anterior chamber. He was also given an intravenous injection of T.A.B. vaccine. The hypopyon was syringed out of the anterior chamber with the penicillin solution but enough of the solution was left to maintain the anterior chamber. Complete cure was obtained in ten days.

(d) Injection into the tissues was carried out in all cases of acute dacryocystitis where there was no definite abscess formation and in cases of minor suppurative lid affections. Solutions of 1,000 units per cubic centimeter were used, and cures were obtained in 24 to 48 hours. This method should be applied only after injection of two to four percent novocaine without adrenalin.

(e) Irrigation with a solution of 250 units per cubic centimeter of penicillin in the aftertreatment of an abscessed

dacryocystitis after the abscess had been opened.

Creams. The application of cream seems to be the only satisfactory method for out-patient treatment. A standard strength of 250 units per gram in a 4-gram tube can be kept at room temperature for a period of about three weeks.

Typical cases in which penicillin cream was used are as follows: (1) Acute conjunctivitis with or without corneal ulcers; (2) marked ectropion with severe chronic infection of the conjunctiva; (3) blepharitis; (4) recurrent styas; (5) eversion of the lacrimal punctum.

In acute conjunctivitis complete cure was obtained in eight to twelve days with application of penicillin cream in the conjunctival sac every four hours. Improvement occurred after the third day.

Recurrent styas respond excellently to penicillin treatment.

Interrupted treatment was most satisfactory in cases of chronic blepharitis. Application was used three times daily at first and after a 10-day interval twice daily.

Two patients with hypopyon ulcer who refused hospitalization were treated with penicillin cream at intervals of three hours. Both were cured in three weeks.

Powders of 2,000-units-per-gram potency were used in some cases of corneal ulcer and acute dacryocystitis after incision. Penicillin powder applied to the conjunctival sac is a very satisfactory method of treating torpid ulcers. (References.)

Edna M. Reynolds.

Reeves, R. J. Roentgenotherapy and radiotherapy for lesions about the eye. *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Sept.-Oct., pp. 120-123.

Roentgenotherapy and radiotherapy for lesions about the eye are always attended by some danger. Beta rays and mild X rays are most easily used, because their penetration is superficial. Corneal ulcers, vernal catarrh, recurrent pterygium, angiomas, tuberculous kerato-iritis, blepharitis, chronic conjunctivitis, epitheliomas, and lymphomas, are responsive to this type of treatment.

Vernal catarrh has been treated with a one-half erythema dose every two weeks, following the application of a local anesthesia, with satisfactory results. Chronic blepharitis is given 100 to 150 r weekly, for four or five doses. Fresh corneal scars respond to less-than-erythema doses over a long period of treatment. Tuberculosis of the anterior segment of the eye responds favorably to small doses of X rays or beta rays. Corneal epitheliomas are occasionally radio-sensitive. Epitheliomas of the lid should be excised and the area exposed to beta rays or mild X rays. Lymphoma or angioma may be similarly treated. Coöperation between radiologist and ophthalmologist is essential. Edward Saskin.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Bender, M. B. Polyopia and monocular diplopia of cerebral origin. *Arch. Neurol. and Psych.*, 1945, Nov.-Dec., p. 323.

This very difficult article describes in detail the symptoms, physiology, and pathology of polyopia and monocular diplopia. Four illustrative case reports

are presented in detail. The polyopia is due indirectly to imperfect fixation which, in turn, is due to defective macular vision. The difficulty of fixation further stimulates formation of new maculas, and in attempting to fixate, the eyes are involved in increasing amplitudes of excursion. This increase in ocular movement causes almost simultaneous stimulation of the new macular areas with the resultant polyopia.

Morris Kaplan.

Bernstein, F., and Bernstein, M. Law of physiologic aging as derived from long range data on refraction of the human eye. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 378-388.

As reported in earlier publications by Bernstein and his collaborators, Hiedemann and Steinhaus, a statistical correlation exists between presbyopia, as measured by the gradual loss of power of accommodation, and the length of life.

From the files of Dr. John E. Weeks, former head of the department of ophthalmology of New York University, 3,000 cases were selected, in which the development of refraction and the changes in prescriptions could be followed through periods ranging from six years to over 40 years, covering ages from 35 years to the highest calendar ages. From these 3,000 cases were selected 344 in which presbyopia had been present more than 12 years and 6 or more prescriptions had been given. In none of these cases were there any pathologic traits nor more than 1.5D. of myopia; in all visual acuity was 20/20 by the Snellen test.

The authors present learned and technical conclusions, which are difficult to abstract. R. W. Danielson.

Burian, H. M., Walsh, R., and Bannon, R. E. Incidence of significant

aniseikonia. *Amer. Jour. Ophth.*, 1946, v. 29, Feb., pp. 201-203. (1 table, references.)

Carlesberg, Olof. Pathogenesis of sulfonamide myopia. *Acta Ophth.*, 1942, v. 20, pts. 2-4, pp. 275-292.

A detailed report is given of four carefully studied patients. The author concludes that the myopia is due to changes in the lens, and not to ciliary spasm. The range of accommodation was normal. The depth of the anterior chamber, diminished in all cases, is attributed to a swelling of the lens. A slight rise in intraocular pressure is also interpreted as a sign of increased volume of the lens. The three eyes examined after instillation of a mydriatic gave no indication of a relaxation of a spasm of the accommodation. In one case a negative spherical aberration was found after homatropine instillation, and in another case a positive spherical aberration appeared as the drug-induced myopia cleared. The seat of the lens changes is predominantly the lens nucleus. Ray K. Daily.

Fieandt, Olof. A case of sulfanilamide myopia, and an investigation of its pathogenesis. *Acta Ophth.*, 1942, v. 20, pt. 1, pp. 24-39.

A review of the literature and a report of a 23-year-old student nurse who developed a transitory myopia after the ingestion of 0.5 gm. of sulfanilamide is presented. Interested in elucidating the pathogenesis of the process, the author made careful studies of the refraction and the range of accommodation while the myopia was clearing. He also determined the effect of homatropine and eserine on the refraction and accommodation. Since the patient had to take another dose of sulfanilamide, the author decided to utilize this opportunity for research. A careful

study of her refraction, fields, and tension preceded the sulfanilamide ingestion. Then the right eye was atropinized and the left eye used as a control. After the ingestion of the drugs the refraction, range of accommodation, and the effect of eserine and homatropine were studied during a period of four days, at the end of which the refraction returned to normal. The data show that myopia appeared in both eyes, but more slowly and less profoundly in the atropinized eye, and that the effect of atropine on the accommodation was not parallel to its effect on the refraction. It appears, therefore, that sulfanilamide counteracted in part the paralyzing effect of atropine on the ciliary muscle. In the light of Tscherning's theory of accommodation, the myopia may be accounted for by a ciliary spasm. To conform with Helmholtz's theory of accommodation, the disparity of the effect of atropine on the refraction and on the accommodation can be explained only by changes in the lens itself, in addition to ciliary spasm.

Ray K. Daily.

Gyoerffy, S. **Experiences with unbreakable contact lenses.** *Ophthalmologica*, 1944, v. 108, July-Aug., pp. 44-67.

One hundred consecutive patients who were fitted by the author with unbreakable contact lenses made from artificial resins in the university eye clinic in Budapest were questioned as to their experiences in wearing these lenses. Forty-seven patients wore the lenses for high degrees of myopia, 25 for keratoconus, and 28 for other refractive errors. Seventeen of the patients did not wear their lenses, and 17 others wore them only on rare occasions. Of the 66 patients who wore their contact lenses regularly or often, 5 were able to wear them four hours

consecutively, 41 wore them from four to 10 hours, while 20 patients could wear them longer than 10 hours. Some had to change the fluid during the periods mentioned. The author discusses the disturbances that are connected with the wearing of contact lenses: fogging due to haziness of the corneal epithelium, formation of bubbles, photophobia, and seborrheic deposits on the surface of resin contact lenses. With the author's technique, no molds are taken from the eyeball of the patient. A set of 50 model forms is used and the form that fits most closely the shape of the individual eye is used for the manufacturing of the final contact lens.

Max Hirschfelder.

Hall, Ronald. **Word blindness: Its cause and cure.** *Brit. Jour. Ophth.*, 1945, v. 29, Sept., pp. 467-472.

The author's interest in the cause and cure of word blindness is more than merely academic since he himself suffered from word blindness as a child and was unable to read until 15 years of age. He learned to read by breaking down all words into their smallest parts and then synthesizing them again by association.

If the patient has difficulty in recognizing single letters, the interaction of tactual and visual perception can be utilized by supplying raised letters. Association can be used by having pictures of objects in the form of letters; for example, a snake forming the letter S. Then when all the letters are known, two-letter words should be learned. He should then read passages in books, picking out all the known two-letter groups such as those underlined in "Now this is the best method." This is a form of analytic vision which will gradually extend synthetic vision so that it will absorb longer words after they have been broken down.

When all two-letter words have been thoroughly mastered in this way, the same procedure should be followed with three-letter words and then with four-letter words in order gradually to extend synthetic vision. When two-, three- and four-letter words have been thoroughly mastered, the important two- and three-letter limbs of words, which are not themselves actually words, should be learned and then passages in books should be read by picking these words out; for example, -ly, -ed, -ing.

The author believes that word-blind children are slightly hyperthyroid, at least until puberty.

Edna M. Reynolds.

Pascal, J. I. Cardinal points in the static and in the dynamic eye. *Arch. of Ophth.*, 1945, v. 34, Oct., pp. 319-320.

As a means of remembering the relative distances between the cardinal points of the eye, the author uses the benzene ring. Starting at the top of the ring and proceeding clockwise the points are designated as focal point 1, nodal point 1, nodal point 2, focal point 2, principal point 2 and principal point 1. Any two opposite sides that are parallel are equal. The distance between the principal point and the corresponding nodal point is equal to the radius of the single refracting surface that can replace the whole ocular system. This potential radius is equal to the difference between the principal focal lengths.

When the eye accommodates it becomes a stronger optical system. This causes a displacement of all the cardinal points. This shift in cardinal points can be visualized and easily remembered by utilizing another benzene ring inside the original ring. This is a thinner and longer ring.

John C. Long.

Weekers, R., and Russell, F. A new ocular test for nutritional deficiency. *Presse Méd.*, 1945, No. 48, Dec. 1, p. 656.

The authors review the role of vitamin A in dark adaptation and point out that avitaminosis A is a cause of night blindness which is reversible on administration of the vitamin. However, it has not been possible to show a close relationship between the level of the carotinemia and the quality of night vision.

In the course of investigations on perimetry in reduced illumination, the authors discovered a retinal phenomenon closely related to that of dark adaptation. They noted that progressive enlargement of the visual field measured under low illumination, as related to the duration of the exposure to darkness, permits a measurement of the retinal adaptation, particularly the adaptation of the rods. They also noted that contraction of the visual field measured under low illumination constitutes a sensitive and precise quantitative test of night blindness. They found that certain nutritional deficiencies, particularly those involving the proteins and the lipids, produced a concentric contraction of the visual field as measured under low illumination. They suggest that this contraction of the visual field is probably due to an alteration in the metabolism of visual purple, but they are unable to conclude that this alteration results from a simple avitaminosis A.

Phillips Thygeson.

OCULAR MOVEMENTS

DeJong, R. N. Nystagmus, an appraisal and classification. *Arch. Neurol. and Psych.*, 1946, v. 55, January, p. 43.

The author gives an up-to-date de-

scription of nystagmus and a classification of nystagmus according to its origin. R. Grunfeld.

Devic, Paufigue, *et al.* **The syndrome of Parinaud, an anatomico-clinical study.** *Ann. d'Ocul.*, 1945, v. 178, May, pp. 177-199.

This syndrome includes paralysis of binocular vertical movements and always involves the superior part of the cerebral peduncles. The lesion may be small and extremely limited. Depending on the location of the lesion in the white commissure posteriorly or the juxtacommissural region, it is bilateral and symmetrical or unilateral and asymmetrical. A man, aged 37 years, who had received a bullet wound in the left temple some 20 years previously, developed a Weber syndrome (right hemiplegia and left third-nerve paralysis) with Parinaud's syndrome. Lateral eye movements were normal. The vision in the right eye was 20/30 and in the left eye, 20/20. Brain sections showed the expected lesion. (8 figures, references.) Charles A. Bahn.

Dupuy-Dutemps, L. and P. **The function of convergence in concomitant strabismus.** *Ann. d'Ocul.*, 1942, v. 178, No. 2, pp. 49-55.

In a study of more than 200 cases of strabismus, convergence was measured by comparing the deviation for distance and near with a perimeter. In convergent strabismus normal convergence was present in 70 percent, diminished convergence in 20 percent, and no convergence in 10 percent. In divergent strabismus normal convergence was present in 42 percent, diminished convergence in 40 percent, and no convergence in 18 percent. The pupillary-convergence reaction was frequently absent if convergence was absent. Convergence may be present if binocular

single vision does not exist. In convergent strabismus with diminished convergence a full operative correction should be avoided because it may be followed by crossed diplopia for near. Charles A. Bahn

Kirby, D. B. **The surgical treatment of strabismus.** *Arch. de la soc. para evitar la Cequera en Mexico*, 1945, v. 3, p. 123. (See *Amer. Jour. Ophth.*, 1946, v. 29, April, pp. 408-421.)

Jerome B. Thomas.

Lancaster, W. B. **What is orthoptics?** *Jour. Amer. Med. Assoc.*, 1946, v. 130, Feb. 16, p. 407.

Orthoptics is the art of teaching patients how to use their eyes properly. At birth the neuronc pathways involved in vision are imperfectly developed. Development may not progress in the normal or ideal way. Obstacles may turn the course of development into wrong channels. The duty of the orthoptic technician is to lead the patient to the acquisition of normal and useful habits and reflexes, and to teach him to coördinate and to control the reflex responses to his environment. The technician does not strive to strengthen allegedly weak muscles.

A major amblyoscope, stereoscope, prisms, and small accessories are indispensable. Glasses may help but are not indispensable. A surgical operation often saves much time and sometimes makes orthoptic training successful when it would be hopeless without surgery. R. Grunfeld.

O'Brien, F. H., and Bender, M. B. **Localizing value of vertical nystagmus.** *Arch. Neurol. and Psych.*, 1945, Nov.-Dec.

A case report of thrombosis of the anterior spinal artery of the medulla is presented. The symptoms were loss

of function of the pyramidal tract on the opposite side and vertical nystagmus. It was decided that the nystagmus had no localizing value other than to place the lesion in the brain stem.

Morris Kaplan.

Scobee, R. G., and Green, E. L. A center for ocular divergence; does it exist? *Amer. Jour. Ophth.*, 1946, v. 29, April, pp. 422-433. (1 figure, 1 table, references.)

Zeligs, M. A., and Joseph, G. F. Unilateral internal ophthalmoplegia: sole clinical sign in patient with syphilitic meningitis. *Arch. Neurol. and Psych.*, 1945, Nov.-Dec.

A very interesting case report is presented wherein a young man who complained of blurring of vision of the left eye is described. Thorough examination was negative except for a large, fixed pupil in the left eye, and a positive Wassermann reaction in blood and spinal fluid. Two courses of penicillin resulted in cure of the patient's lues and of his ocular disturbance.

CONJUNCTIVA

Bangerter, A. Pterygium operation and covering of conjunctival defects. *Ophthalmologica*, 1943, v. 106, Nov.-Dec., pp. 316-320.

The author describes a method whereby recurrence of pterygium can be avoided and the larger defects of the conjunctiva which occur after removal of tumors or cysts can be covered. His drawings show a rhomboid excision followed by undermining and mobilization of a large part of the upper bulbar conjunctiva. The lips of the wound are sutured to the lower

margin of the conjunctival defect so placed that normal conjunctiva lines the corneal margin throughout.

Max Hirschfelder.

Botteri, A., and Sokolić, P. Trachoma treatment with albucid. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 469.

At the University Eye Hospital at Zagreb an unspecified number of trachoma patients were treated with albucid locally and orally. (See also *Schweizer med. Woch.*, 1941, v. 42, p. 1215.) The greatest effect was obtained with combined local and oral medication. A number of patients responded surprisingly well to this treatment, another group less favorably, and a third showed almost no improvement even after three weeks of treatment. In this last group, additional mechanical therapy was necessary. Such cases are not rare but represent a minority of the total.

F. Nelson.

Fischer, I. Albucid treatment of trachoma. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 445.

At the University Eye Hospital at Jena, 23 patients with trachoma were treated without albucid in 1940 until March, 1941, and 17 were treated with albucid from March, 1941, until January, 1942. The author concludes that albucid alone, even in strong doses given locally and orally, cannot cure trachoma though it rapidly allays local irritation. If local mechanical and chemical (copper, alum) treatment is combined with oral albucid medication recovery occurs in half the usual time.

F. Nelson.

Friedman, B., and Gernand, H. Sjorgren's syndrome treated with stilbesterol. *California and Western Medicine*, 1946, v. 64, Jan., p. 31.

A woman, 24 years of age, com-

plained of burning pain in both eyes. The lids were hot and dry. There was no tearing, no photophobia, and no secretion. The complaints were intensified before menstruation. The left thumb was swollen and painful during the previous winter. Local therapy and vitamins gave no relief.

The consulting gynecologist found a dry vagina with pale and thin mucous membranes. The body of the uterus was studded with numerous small fibromas. Eventually a subtotal hysterectomy was performed. Both ovaries were found to be cystic and scarred to an extreme degree. Three mg. stilbesterol with 100 mg. vitamin C per day was prescribed and the patient now feels comfortable and all eye symptoms have disappeared. If she omits the stilbesterol or takes less the ocular discomfort returns. R. Grunfeld.

Gjessing, H. G. A. **Primary cancer of the conjunctiva.** *Acta Ophth.*, 1942, v. 20, pt. 1, pp. 14-23.

The literature is reviewed and a case of carcinoma of the limbus in a 63-year-old man is reported. The mother of the patient died of carcinoma of the stomach, and the patient previously had had a rodent ulcer of the lip. He attributed the bulbar carcinoma to a blow on the eye with a piece of wood; the lump appeared three months after the injury and was excised eight months later. It recurred, and was excised again six years later, this time followed by radium irradiation. It is emphasized that surgery should always be followed by irradiation. (Photograph.)

Ray K. Daily.

Glowatzky, F. **Experiments with sulfonamide therapy in trachoma.** *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 449.

In the German University Eye Hos-

pital at Prague the effect of sulfa drugs was tested in 145 trachoma patients, 17 of whom were treated in the hospital itself. One hundred twenty-eight were German-Bessarabian inmates of a relocation camp. Eubasin (sulfapyridine) and albucid (p-amino-benzo-sulfoacetamide) were used. They were given orally in large doses for ten days followed by a rest period of six days. One hundred and one cases required two such courses, 39 needed three courses, and in 11 a fourth became necessary. After nine weeks 119 patients were free from symptoms. Glowatzky had the impression that the effect of eubasin manifests itself earlier than that of albucid but in the long run no definite difference between the two substances was noted. Additional local treatment with sulfa drugs seems to hasten the healing process. In seven cases of follicular conjunctivitis treatment with sulfonamides proved to be ineffective. (5 tables, bibliography.) F. Nelson.

Gogler and Mielke. **Treatment of trachoma with sulfonamides (albucid, eleudron, eubasin, and cibazol).** *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 402.

Experiments with sulfa drugs were carried out in two hospitals in different localities; namely, Greifswald on the Baltic and Linz on the Danube. At the Linz Hospital 535 patients between one and 80 years of age were treated. The average time of treatment was 47 days; 70.47 percent were cured after three to seven weeks, 19.25 percent after 13 weeks, 9.16 percent after 17 weeks, 0.74 percent after 22 weeks, 0.37 percent required 22 to 26 weeks of treatment. First all patients received albucid, later eleudron was used. The effect of both drugs was about the same. Almost invariably the acute inflammatory symp-

toms improved as soon as treatment with sulfonamides was given but soon the condition became stationary. Local treatment consisted of instillation of 10-percent targesin twice daily and mechanical treatment of follicles with Knapp's roller forceps. The time of observation of not more than a year was insufficient to permit of definite conclusions.

At the Griefswald Hospital 33 of 60 trachoma patients were selected for treatment with sulfonamides. Thirteen patients were given albucid, 11 eubasin and nine cibazol. Rapid improvement of the irritation was observed. However, the follicles disappeared in only two cases in which the diagnosis trachoma was not absolutely certain. Though the sulfonamides undoubtedly represent an enrichment of our therapeutic armamentarium they do not fundamentally change the aspect of the disease. They should be applied as adjuvants in patients with acute irritation and secretion as well as in those with fresh corneal complications. Where only follicles are present and little irritation immediate mechanical treatment is indicated. Ambulant treatment with sulfonamides is not advisable because the dosage must be supervised closely. (1 plate with 9 color photographs, 2 photographs, 1 table.)

F. Nelson.

Kornerup, Tore. Histamin blood content in a case of allergic conjunctivitis. *Acta Ophth.*, 1942, v. 20, pt. 1, pp. 56-62.

The author reports a case of allergic conjunctivitis, with an increased histamine blood content, relieved by treatment with histaminase. The interesting feature of this case is the parallelism between the rise in the blood histamine and the clinical recurrence of symptoms. Ray K. Daily.

Lorenz, R. Reëxamination of trachoma patients treated previously with albucid. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 414.

Of 43 trachoma patients reported in a previous article (*Klin. M. f. Augenh.*, v. 106, pp. 302-306), who had been treated with albucid, 23 were re-examined four to 21 months after they had been released. Recurrences were not observed in any. One patient had been treated with uliron instead of albucid. Follicular, catarrhal and vernal conjunctivitis and paratrachoma were not influenced by sulfonamides.

F. Nelson.

Lugossy, G. The chemotherapy of trachoma. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 474.

At the University Eye Department at Szeged, 31 trachoma patients, of whom 21 were hospitalized, were treated with albucid. The patients were divided into 4 groups and given albucid in different doses by mouth and locally. The effect of albucid is favorable no matter what method of medication is used. The effect is most pronounced in patients with acute inflammation in any stage of trachoma. Spectacular success is achieved in trachoma complicated by pannus. Albucid in large doses also has diagnostic merit: rapid healing of acute ophthalmic inflammation rules out trachoma. Trachoma does not heal so rapidly. Since the introduction of albucid the average stay in the hospital was reduced to three weeks, and in many cases was unnecessary. (References.)

F. Nelson.

Lauber, H. Sulfonamide treatment of trachoma. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 460.

At the Krakau Eye Hospital several sulfonamides were used in combating trachoma. Essentially the effect of

these preparations was identical. The combination of medico-mechanical procedures with internal sulfonamide medication shortens the healing process considerably. (4 color photographs.) F. Nelson.

Meesmann, A., and Bruhn, A. Trachoma treatment with sulfonamides. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 464.

Up to 1940 only a negligible number of cases of trachoma had been seen at the University Eye Hospital at Kiel. With the influx of foreign labor, mostly Poles, this number increased noticeably. In June, 1941, sulfanamide therapy was introduced. Seventeen patients, among them six with fresh lesions were treated with albucid; tetracid, and cibazol. In no case were the sulfonamides alone effective. Other medicinal and mechanical methods were always necessary to complete recovery. F. Nelson.

Meisner, W. Treatment of trachoma with sulfonamides. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 458.

At the University Eye Hospital at Munich a number of trachoma patients, mostly repatriated German-Bessarabians were treated with eubasin. Meisner was under the impression that the drug influenced the superimposed conjunctivitis and pannus favorably. Granules showed only temporary, if any, improvement. Not a single case of trachoma, even a fresh one, could be cured with the drug. The hospital staff felt compelled to resort to the old methods, not only in order to shorten the time of treatment but also to accomplish an eventual cure.

Miao, T. Y. Trachoma among primary school children. *West China Med. Bull.*, 1945, v. 2, June 15, p. 35.

In the fall of 1944 a survey was conducted in 11 primary schools in and around Chengtu to discover the prevalence of eye diseases among the children. A total of 4,993 children were examined of whom 2,802 were male and 2,191 female. Nearly one third of the children, 1,600, had some kind of ocular ailment; 1,002, or 20.1 percent, had trachoma. (5 tables.)

China Medical Journal.

Miranda, G. Treatment of trachoma with sulfonamides. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 482.

Forty-seven trachoma patients between the ages of 12 and 45 years received ambulant treatment with 0.03 gm. sulfonamide per kg. body weight daily over a period of 15 days followed by a rest period of eight days. This regimen was continued over a second, third, and sometimes fourth and fifth cycle. Additional local treatment consisted of atropine only when the cornea was involved. In 12 cases a 5-percent ointment of the drug was administered. All eyes with corneal complications improved. Of those with conjunctival trachoma only 29 improved and 18 remained unchanged. Complete cure with scar formation was observed only once. Improvements were usually observed after eight days. (Bibliography.)

F. Nelson.

Osterberg, G. Lucosil for local treatment in ophthalmology. *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 321-336.

Lucosil is a water-soluble sulfonamide, neutral in reaction, and marketed in a 40- to 4-percent aqueous solution. Osterberg investigated its usefulness in local application in ophthalmology, experimentally and clinically. The investigation demonstrated that except in allergic patients, it is harmless and nonirritating to the conjunctiva, that

it is therapeutically effective in experimental keratitis, and that it is clinically effective in the treatment of various forms of keratitis, chronic blepharoconjunctivitis, and acute dacryocystitis. (6 illustrations.) Ray K. Daily.

Purtscher, Ernst. Trachoma therapy with albucid. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 442.

From October, 1940, until December, 1941, 29 of 41 patients with old trachoma received hospital treatment with albucid at the University Eye Hospital at Graz. Five patients were treated locally with albucid ointment only and without noticeable benefit. The other patients received albucid orally (3 tablets 3 times daily for 7 consecutive days); in nine patients this dosage was sufficient, in ten it was repeated once, in two, thrice and in three, four times. Usually after this regimen one tablet daily was given. As additional local treatment boric acid or zinc drops and 10-percent albucid ointment were used. The catarrhal condition disappeared rapidly. The papillary hypertrophy and pannus improved, follicles often diminished, and corneal ulcers healed. Cicatrizing of the trachomatous conjunctiva, which Purtscher regards as the safest clinical criterion of the healing process, was never achieved with albucid therapy. Albucid, like other sulfonamides, is a valuable help in combating fresh trachoma, but it does not seem noticeably to influence the deep proliferating inflammation of the conjunctiva.

F. Nelson.

Rohrschneider, W. The effect of albucid in trachoma. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 430.

In 53 cases of trachoma in different stages the effect of albucid on the con-

junctival and corneal lesions was studied systematically. About one third of the lesions were influenced so favorably that one could speak of a clinical cure. The treatment consisted of huge doses of albucid for three days alternating with periods of rest. Two or three courses of this kind with a one-week rest period between were necessary. Rohrschneider concludes that albucid proved valuable in the treatment of trachoma, though additional mechanical and chemical treatment is sometimes needed. Because of recurrences, the possibility of absolute cure can be estimated only after years of observation. Albucid was tolerated well by all patients. F. Nelson.

Schindler, R. Experiments with albucid as a therapeutic agent against conjunctival infections, especially trachoma. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 420.

At the First University Eye Hospital in Vienna, 12 patients suffering from trachoma were subjected to ambulant treatment with albucid (p-amino-benzosulfonacetamid). Seven patients with newly acquired trachoma were given albucid in comparatively large doses over a period of three days, followed by a rest period of three days, after which the same treatment was repeated. Since albucid is eliminated from the body in four days the patient remains under the influence of the drug. In advanced trachoma the treatment consisted of continuous doses (0.03 gm. per kg. body weight daily) over a period of three to four weeks followed by a rest period of at least four weeks. Fresh cases manifested no spectacular objective improvement during or after the first course of treatment. However, all of the patients were made more comfortable. During

the second course the improvement was rather impressive and even more so during the third. In some cases a fourth and fifth course became necessary. Local treatment was not administered in any case. Photophobia and discharge disappear rapidly in early trachoma. Granules and papillary hypertrophy disappear more slowly, usually in one or two months after the conclusion of the albucid medication. Incipient pannus undergoes involution early. Five patients with old trachoma who had all been treated with copper sulfate, and two of whom had corneal ulcers, improved after the second week of treatment with albucid. Pannus disappeared gradually. Complicating infections that were present in all these patients were eliminated within four to eight days. The granules were reduced in size and number, and the conjunctiva became pale after four weeks of albucid without local therapy. The author prefers not to speak of an absolute cure of trachoma by means of albucid, but calls the condition "inactive trachoma." All patients with nontrachomatous conjunctival inflammation were cured without local treatment in two to four days.

F. Nelson.

Scheyhing, H. The treatment of trachoma with albucid. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 436.

The resettlement of large numbers of racial Germans (*Volksdeutsche*) from regions outside the Reich, especially from eastern countries, made the establishment of clearing camps and special trachoma clinics necessary. In the clearing station under the direction of the Würzburg University Eye Hospital, 82 patients with trachoma received treatment and all but six of them have recovered. A little more than one third of the fresh cases and two thirds

of the older ones were clinically cured with albucid therapy. In most cases treatment for two to six months was sufficient. Since the percentage of real cures was relatively small, Scheyhing's conclusion is that albucid therapy does not fulfill expectations. F. Nelson.

Seefelder, R. Sulfonamide-therapy of trachoma at the University Eye Hospital at Innsbruck. *Klin. M. f. Augenh.*, 1942, v. 108, July-Aug., p. 466.

Four cases of trachoma were treated with sulfonamides. Corneal trachoma responded most favorably to the drugs. Subconjunctival application of pron-tosil did not hasten the healing process. Of two additional patients seen during the printing of this article one did not continue treatment; the other showed marked improvement of his extensive pannus and improvement of vision but additional local mechanical treatment was needed.

F. Nelson.

Weiszlovits, E. Treatment of ophthalmia neonatorum and serpiginous ulcer with sulfonamides. *Ophthalmologica*, 1944, v. 108, Sept., pp. 121-128.

Ophthalmia neonatorum was successfully treated with a 15-percent albucid solution. In adults the internal use is recommended as additional medication. Local and internal treatment of serpiginous ulcers by sulfonamides was effective.

Max Hirschfelder.

CORNEA AND SCLERA

Lo, L. Y., and Tang, P. C. Dendritic ulcer of the cornea. *West China Med. Bull.*, 1945, v. 2, June 15, p. 67.

This paper embodies the report of seven cases of dendritic ulcer of the cornea. The etiology and treatment of the disease are discussed. It is believed

that a virus is the causative agent. Malaria is also an important contributing factor. At least five of the seven patients had malarial fever shortly before the onset of the ocular affection. (19 diagrams, references.)

China Medical Journal.

Sun, K. S. Nodular scleritis. *West China Med. Bull.*, 1945, v. 2, June 15, p. 56.

Five cases of nodular scleritis are reported. The patients were admitted to the Chengtu Eye, Ear, Nose, and Throat Hospital, where careful studies were made and thorough treatment given. Four of them were male and one female, their ages ranged between 20 and 30 years. In two of them the lesion was apparently caused by syphilis and in two by tuberculosis; in the other by a focal infection. All the patients were improved upon discharge. Two patients had complications, one had early iritis, the other keratitis, and both recovered. (References.)

China Medical Journal.

Weiszlovitis, E. Treatment of ophthalmia neonatorum and serpiginous ulcer with sulfonamides. *Ophthalmologica*, 1944, v. 108, Sept., pp. 121-128. (See Section 5, Conjunctiva.)

Westerlund, E. Keratitis nummularis (Dimmer). *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 367-378.

A review of the literature, and a report of the first eight cases of epidemic keratoconjunctivitis in Scandinavia are presented. The first patient, seen in 1940, developed the disease after a brief sojourn in Germany. The other seven cases occurred in the summer and fall of 1942.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Birkhaeuser, R. Eye diseases through infectious foci in the teeth. *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 3-16.

Ten cases of inflammation of various parts of the eye (cornea, uvea, optic nerve) are described individually. In each patient X-ray examination revealed defective teeth, and the eye recovered after the dental focus was treated.

Max Hirschfelder.

Chan, Eugene. Polycoria. *Nat. Med. Jour. China*, 1945, v. 31, April, p. 137.

The two oldest cases of polycoria in China are those noted by Szu-ma Chien (born 145 B.C.) who stated that Emperor Shun (2255-2205 B.C.) as well as King Hsiang Yu (232-202 B.C.) had double pupils. From other ancient Chinese sources, the author has brought to light eight additional cases. He calls attention to the classification of polycoria: (1) Polycoria vera; (2) Iridodehiscence; (3) Iridodiasis. He examined three patients with polycoria. A girl, three years of age, had true polycoria in her right eye. The other two cases of abnormal pupil were not typical. The abnormality was evidently caused by persistent pupillary membrane, and in one of them there was localized hypoplasia of the iris stroma as well.

China Medical Journal.

Godtfredsen, Erik. Reëxamination of central ruptures of the choroid. *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 335-350.

The close relation of the pathogenesis of rupture of the choroid, Ber-

lin's edema; subretinal hemorrhage, and macular hole is pointed out. A follow-up study of 12 cases of rupture of the choroid, which are briefly reported, demonstrates the seriousness of the prognosis in such accidents. The final central visual acuity was below 6/60 in seven patients. In five other patients, after transitory visual impairment the final vision was 6/6 in four, and 6/12 in the other one; three of the five eyes had ruptures through the fovea. The visual improvement usually takes place within the first few weeks. Visual impairment which persists longer than two months is apt to remain permanent. Particularly interesting is a patient whose right eye sustained bulbar contusions twice within six months. The first injury produced five choroidal ruptures, one of them through the fovea, and the second resulted in a hemorrhage in the fovea. The final visual acuity, observed for a period of two years, was 6/6.

Hallett, J. W. Report of a case of iridocyclitis associated with chickenpox. *Amer. Jour. Ophth.*, 1946, v. 29, April, pp. 459-460. (Reference.)

Holst, J. C. Congenital myosis. *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 494-505.

A case of congenital familial myosis is reported. The symptoms were pain in and behind the eyes and at the back of the head, decreased vision, and hemeralopia. The patient has been using a weak solution of scopolamine with relief of symptoms for 45 years; the symptoms recurred whenever she attempted to do without the scopolamine. A brother and sister had similar eyes, and after their death these were examined microscopically. The sections show a faulty or incomplete develop-

ment of the dilator of the pupil. Wherever a trace of the muscle was found it had no peripheral attachment, so that it could not function.

A preliminary microscopic study of another case is reported. A child, 2½ years of age, with congenital cataracts and myosis, had iridectomies performed on both eyes. The right lens was injured during surgery; the eye developed an inflammation and was enucleated. The microscopic sections showed no trace of the dilator of the pupil, and a part of the ciliary muscle was found in the periphery of the iris stroma.

Of 13 cases found in the literature, only the eye described by Redslob had been examined histologically, and it had defective iris musculature. The familial occurrence is shown by Holth and Berner, who report three affected children in a family of 11, and by Sautter, who found five in one family.

Ray K. Daily.

Kiss, F. The blood circulation of the eye. *Ophthalmologica*, 1943, v. 106, Nov.-Dec., pp. 226-250.

By injecting eyes of man, rabbits, dogs, and cats with dyes through the ophthalmic artery and through the facial vein the author studied the branching, topography, and interrelation of the blood vessels in various parts in the eye. The vascular system of the ciliary body consists of two parts: (1) the broad vessels of the ciliary process, which are similar to the broad veins of the iris, and (2) the narrow vessels of a so-called ciliary plexus in the region of the ciliary muscle. The veins of the ciliary process end in the system of the choroid, whereas those of the ciliary plexus penetrate the sclera and end in the episcleral system. The author believes

that the blood vessels of the iris do not serve to resorb the aqueous, but that such resorption takes place in the ciliary plexus. The plexus may be considered as a second capillary region of the broad iris veins. The vessels of the ciliary processes, on the other hand, take part in the production of the aqueous. On the basis of experiments with injection of dyes into the anterior chamber, the author expresses the opinion that the canal of Schlemm does not play an important part in the resorption of the aqueous humor. The circulation of the blood and of the aqueous normally in a labile balance which is primarily regulated by the arterial influx. The article is very detailed and there is much speculation about the circulation and its relation to glaucoma, in which this labile balance is disturbed. Max Hirschfelder.

Rasmussen, Knead. Acquired ectropion of the uvea. *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 310-320.

A detailed histopathologic study of 12 enucleated eyes which had ectropion of the uvea of varying degree, from small to total, is reported. These eyes had peripheral anterior synechiae corresponding in extent to the ectropion; a membrane on the anterior surface of the iris, varying from a very fine veil to a very thick membrane; folds in the anterior layer of the iris; more or less pronounced atrophy of the iris; ectropion of the sphincter of the pupil in a lesser degree than that of the pigment epithelium; and proliferation of the pigment epithelium. A single pathologic process cannot explain the development of ectropion of the uvea. It seems probable that several factors cooperate in its production. Clinically, its appearance suggests progression of the primary disease. Tumors, glaucoma,

trauma, or severe hemorrhages may give rise to a slow chronic uveitis, with the formation of anterior synechia, exudate which shrinks subsequently, atrophy of the iris, and degeneration and proliferation of the pigment epithelium. These processes lead to ectropion of the uvea. Ray K. Daily.

Redslob, M. E. A strange case of internal ophthalmoplegia. *Ann. d'Ocul.*, 1945, v. 178, June, pp. 121-123.

A smoking mixture used to relieve asthmatic attacks was mixed by the patient with his pipe tobacco. It contained belladonna and enough was absorbed in the saliva to produce mydriasis and cycloplegia. Charles A. Bahn.

Waardenburg, P. J. Chorioideremia as an inherited anomaly. *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 235-274.

The following conclusions are based on an exhaustive review of the literature.

Chorioideremia occurs in two clinical forms: an early congenital infantile form, and a late juvenile form.

The early form is typical. Except in the foveal region, the choroid is entirely absent, and the fundus is white. In less typical cases choroidal vestiges and pigment spots may be seen in the periphery of the fundus. The condition remains stationary for a long time; finally, however, central vision is lost. The anomaly is probably due to a disturbance in the development of the primitive choriocapillaris and the long posterior ciliary arteries, and a simultaneous interference with the pigment development in the outer layer of the secondary optic vesicle. Night blindness and constriction of the visual fields are present from early infancy, due to the involvement of the neuroepithelial layer. This form of the disease is fre-

quently associated with a moderate degree of myopia. The second form is characterized by a slowly progressive course, with deterioration of vision, due to the confluence of dystrophic areas. This form resembles a typical gyrate atrophy of the choroid and has no connection with myopia.

Genetically both forms are probably sex-linked. The infantile form appears to be recessive, and the late juvenile form intermediary.

There is not sufficient evidence in the literature for the assumption that both types are transmitted through an X-chromosome.

Chorioideremia is not clinically nor biologically the end stage of gyrate atrophy. Occasionally the end stages of gyrate atrophy, particularly that occurring in high myopia with peripapillary atrophy, may resemble chorioideremia.

The data in the literature are too inadequate to permit of definite conclusions. It is desirable that all relatives of patients be examined as early as possible, and repeatedly, and that the eyes of all still-born males in the siblings be examined microscopically. In reporting cases in which the disease is apparently transmitted from father to son, the history should be clear on the question of consanguinity in the parents.

GLAUCOMA AND OCULAR TENSION

Kjerrumgaard, Erling. On tonometry. *Acta Ophth.*, 1942, v. 20, pts. 3-4, pp. 357-366.

This investigation was concerned with the gaging of tonometers, and with the effect of manipulative errors on the accuracy of tonometric measurements. The author concludes that the two models of the Schiøtz tonometer

are equally reliable. It is essential that the instrument should be placed accurately, centrally on the cornea, and in line with the optic axis. An inclination of 15 degrees from the center of the cornea does not invalidate the findings, but an inclination of 30 degrees makes the readings worthless. It is important that the foot be in close contact with the cornea. The patient's coöperation in looking quietly and not squeezing the lids around the instrument is essential. Squeezing the lids disturbs the relation between the instrument and the cornea and makes the reading unreliable. (Graphs.) Ray K. Daily.

Owens, E. U., and Woods, A. C. Further studies on the use of furmethide in the treatment of glaucoma. *Amer. Jour. Ophth.*, 1946, v. 29, April, pp. 447-450. (3 tables, references.)

Radnot, Magda. Male gonads and intraocular pressure. *Ophthalmologica*, 1944, v. 107, May-June, pp. 282-289.

Experiments with rabbits showed that castration caused hypotony of short duration. Unilateral castration, unilateral ligation of the ductus deferens, and X ray treatment of one testicle caused hypotony of the contralateral eye. Diminished or lost function of the testicles seems to alter the response of the ocular tension to extract of the anterior pituitary lobe. This extract normally lowers the pressure but stimulates a rise of the ocular tension in castrated animals.

Max Hirschfelder.

Radnot, Magda. The suprarenal gland and the intraocular pressure. *Ophthalmologica*, 1944, v. 108, Sept., pp. 137-139.

Disturbances in the hormone-producing organs may affect the intraocular pressure. Extirpation of the suprarenal

gland brought about a lowering of the intraocular pressure on the side of the extirpated gland. This differs from the behavior after extirpation of the sexual glands, which is followed by a contralateral lowering of the intraocular pressure.
Max Hirschfelder.

Weekers, R. Myopia and traumatic hypotony. *Ann. d'Ocul.*, 1945, v. 178, June, pp. 236-241.

A boy, aged 11 years, who was injured twice in the same eye, first by a stone and six weeks later with a fist, developed a myopia of 3.5D. to 5D. and hypotony after each injury. Following the use of atropin, both subsided in about six weeks, with normal vision. The author assumes that the myopia and the hypotony were due to a relaxation of the zonule of Zinn following a hyperemia and edema of the ciliary body.

CRYSTALLINE LENS

Bischler, V. Binocular vision in the aphakic patient. *Ann. d'Ocul.*, 1945, v. 178, July, pp. 273-279.

In the opinion of Deverger and Velter cataract extraction in the first eye is usually a necessity; that of the second eye, a luxury. In 50 patients successfully operated upon because of congenital or senile cataracts in both eyes, 49 had binocular vision and 47 stereoscopic vision. The ages ranged from 28 to 81 years, the time between operations on both eyes, two to eight years, and the corrected vision after operation on both eyes, from 0.3 to 1.0. Patients with cataracts due to trauma, disease, and with marked oculomotor anomalies were eliminated from the series. The author concludes that cataract operation of the second eye, generally speak-

ing, is not a luxury but also a necessity, if binocular vision is probable.

Blake, E. M. Congenital membranous cataract. *Amer. Jour. Ophth.*, 1946, v. 29, April, p. 464.

Cherif, M. D. Anesthesia in cataract operations. *Arch. de la Asoc. para evitar la Ceguera en Mexico*, 1945, v. 3, p. 167.

After a brief historical review of the use of general and local anesthesia in ocular surgery, the author states his personal conclusions:

He prefers cocaine in 4-percent solution for local operations and for cataract extraction, and disapproves of the additional use of retrobulbar injection of novocaine, unless especially indicated by complicating factors, such as pain and increased tension. He objects to the use of retrobulbar injections because of the possibility of hemorrhage from lesions of the retrobulbar vessels, injury to the optic nerve, and dislocation of the globe to such a degree as to require fixation of the superior rectus, with consequent deformity of the cornea and loss of vitreous. The author employs palpebral akinesia only under special conditions, but, when indicated, he prefers the technique of O'Brien to that of Van Lint, because it avoids infiltration of the lids and consequent edema. He condemns the systematic practice of external canthotomy, and fixation of the superior rectus.

Godtfredsen, Erick. Electric cataract and electro-cardiographic changes after

electric shock. *Acta Ophth.*, 1940, v. 2, pt. 1, pp. 69-79.

Visual disturbances in the right eye and electro-cardiographic changes developed in a farmer aged 23 years, who was struck above the right eye by a wire which carried a 220-volt current. The lids of the right eye were burned, and the anterior surface of the lens was dotted with numerous small, slightly elevated vesicles. Eight days later the lens opacities assumed the form of a rosette which involved the portion of the lens which was in contact with the pupillary border, and left the periphery and center transparent. The vision was reduced to 6/12. The opacities disappeared within four weeks, with recovery of normal vision. At this time a subcapsular, more centrally located, irregularly reticulated opacity was found; it became progressively denser, and at the end of three months vision was reduced to 6/12. These findings are similar to those reported by Croci. The lens changes are attributed to an electrothermal epithelial injury to the lens capsule, the opacities being the result of a disturbance in nutrition. (Illustration.)

Henkes, H. E. The distribution of vitamin C in the lens of the eye. *Ophthalmologica*, 1944, v. 108, July-Aug., pp. 11-43.

By means of microtitration according to Glick and Biskind as well as by histochemical methods according to Giroud and Leblond the lenses of various animals (cattle, rabbits, guinea pigs, rats, mice, and cats) were examined for the vitamin-C content at various levels. The author cut a cylinder from the lens, with a trephine, cut the cylinder in 10 sections on a microtome and measured the vitamin-C content of the sections.

Lens capsule and lens epithelium have little vitamin C. The peripheral cortex of young lenses has the highest ascorbinic-acid content, which decreases slowly towards the inner cortical parts and decreases still more, and more abruptly, in the lens nucleus. Older lenses have less vitamin C, the peripheral lens cortex (as compared with the inner cortical parts) is relatively poorer in vitamin C and the values in the nucleus may decrease to zero. The distribution of vitamin C at different lens levels varied according to the various groups of animals, but all of them showed higher values in the cortex than in the nucleus. The author investigated the influence of vitamin-C-free diet on the vitamin-C content of the lens in guinea pigs and found that the peripheral parts of the cortex are the first to decrease in vitamin C, that the values in cortex and nucleus reach zero after 10 to 15 days, and that the peripheral cortex shows a rapid recovery of vitamin-C content after 24 hours of a diet containing vitamin C.

Max Hirschfelder.

Radnot, Magda. A rare case of luxation of the lens. *Ophthalmologica*, 1943, v. 106, Nov.-Dec., pp. 312-315.

In an eye which had been injured three months before enucleation the lens was found adherent to the detached and folded retina just in front of the papilla. Presumably the shrinkage of newly formed connective tissue after hemorrhage into the vitreous pulled the lens towards the retina.

Max Hirschfelder.

Shah, M. A. Glass-blower's cataract. *Indian Med. Gazette*, 1945, v. 80, p. 400.

After a short history of glass-blowers' cataract, the author presents his experimental work. He exposed six rab-

bits to varying numbers of 5-minute periods of heat which was free from infra-red radiations. All the animals developed opacities of the peripheral cortex. Since glass-blowers' cataract always occurs axially in the posterior cortex it was concluded that some factors other than the heat radiations were most probably responsible.

Morris Kaplan.

Sobhy Bey, M. Why intracapsular extraction in senile cataract? *Ann. d'Ocul.*, 1945, v. 178, July, pp. 279-286.

Senile cataract should usually be operated upon as soon as it is sure that defective vision will seriously handicap the patient. The advantages and disadvantages of intracapsular, and extracapsular extractions are discussed. Retinal detachment is more frequent after intracapsular, and secondary glaucoma more frequent after extracapsular operations. The technique used by the author is that generally employed in this country. It includes orbital injection and topical anesthesia, akinesia, a superior-rectus thread, complete iridectomy in extracapsular extraction and basal iridectomy in intracapsular, and conjunctival or corneoscleral sutures. Either capsule forceps or Barraquer suction are used in intracapsular extractions. In monocular patients, the extracapsular technique is preferred. In binocular patients with one eye successfully operated upon, the intracapsular method is generally used.

Charles A. Bahn.

Sun, K. S. Suturing of the wound in cataract extraction. *West China Med. Bull.*, 1945, v. 2, June 15, p. 46.

The advantages of applying sutures in cataract surgery are discussed in detail. The author believes that the application of well-chosen and carefully

practiced technique of suturing helps those of limited skill to perform operations satisfactorily. For the last four years the author had used the Stallard suture, with certain modifications, in all the cataract operations performed by himself and others under his instruction. A new method of managing the emptied anterior chamber, before sectioning, is described. (6 diagrams, references.) *China Medical Journal.*

Zeeman, W. P. C. Congenital dislocation of the lens. *Acta Ophth.*, v. 20, pt. 1, pp. 1-13.

Zeeman reviews the histories of 30 patients. If congenital ectopia lentis is left alone the prognosis is poor, because cataract, retinal detachment, glaucoma, myopic changes, and amblyopia are frequent complications. Of 45 untreated eyes, five developed retinal detachment, eight cataract, and five glaucoma. Three eyes had poor visual acuity because of high myopia. Ten eyes were amblyopic. Only 14 of the 45 eyes had visual acuity adequate for work; in two of these it deteriorated subsequently, owing to myopic degeneration in one, and retinal detachment in the other. Zeeman believes that a two-needle discission is the operation of choice. The dislocated lens is difficult to manipulate with one needle. Even with two needles the operation is difficult and must often be repeated several times. Three cases are reported in detail. One patient was treated by discission with two needles, and the result was good visual acuity in both eyes. In the second patient discission was followed by extraction in the right eye, and a loop extraction in the left; the result was vision $\frac{3}{4}$ in the right eye, and atrophy of the globe in the left eye. The third patient developed secondary glaucoma in the right eye.

at the age of 50 years. A loop extraction of the lens, was followed by a postoperative iridocyclitis, with sympathetic ophthalmia, in the left eye. The eyes slowly recovered, and one year after the operation vision was $1/4$ in the right eye and $1/10$ in the left. Four years later the right eye was blind from glaucoma, and the left lens was opaque.

RETINA AND VITREOUS

Bedell, A. J. *Clinical differentiation of emboli in the retinal arteries from endarteritis.* Arch. of Ophth., 1945, v. 34, Oct., pp. 311-317.

Detailed ophthalmoscopic studies and particularly studies of repeated fundus photographs indicate a difference in the fundus picture of embolus and of endarteritis. In embolus of the central retinal artery, the arteries become mere threads, and the veins are greatly reduced in size. In endarteritis, the arteries are rarely so small as in embolism. The arterial walls always have plaques. The retinal edema from embolism is limited to an oval area that includes the disc and macula. In endarteritis the edema usually involves the entire fundus. Six cases of embolism and endarteritis are reported in detail. (9 fundus photographs.)

John C. Long.

Biró, I. *The connection between pigment degeneration of the retina and disturbances of the ear.* Ophthalmologica, 1944, v. 107, March-April, pp. 149-157.

Pigment degeneration of the retina sometimes follows a dominant pattern of inheritance, and at others is recessive. When recessive, particularly in families with intermarriages, disturb-

ances of the hearing are often found. The nervous elements of the inner ear (Corti's organ) and fibers and ganglion cells of the acoustic nerve are affected. One must assume that there is a hereditary and phylogenetic connection between the lesions of the eye and the ear. It is not possible at this time to differentiate histologically the dominant type of pigment degeneration, which is only confined to the eye, and the recessive type, which shows disturbances of the ear, polydactyly, and other abnormalities. Canales, J. S. *Motility of intraocular cysticercus.* Arch. de la Asoc. para evitar la Seguera en Mexico, 1945, v. 3, p. 31.

This study, based on the observation of 11 cases of cysticercus in the vitreous and the subretinal tissues, is of considerable biologic interest, but of only limited interest to the ophthalmologist. The author with infinite patience has conducted examinations of these larvae, at frequent intervals, to determine the character and speed of their contractions. He finds that the speed of contraction diminishes from almost constant undulatory movements in cases of intraocular infestation of a few days' standing, to complete cessation after about two years. He describes seven varieties of movements. These are illustrated by a series of 10 photographs of a subretinal cysticercus located near the optic disc. Careful and extensive explanatory notes are added. In a cysticercus eight months old he conducted observations with the electric ophthalmoscope, and the biomicroscope before and after instillation of atropine, pontocaine, and cocaine. No definite conclusions were reported. However, it was noted that changes of motility of the

parasite began about two minutes after the instillation of the drugs, which suggests that the drugs were rapidly absorbed into the interior of the eye ball. (10 references.) Jerome B. Thomas.

Chan, Eugene. Glioma. West China Med. Bull., 1945, v. 2, June 15, p. 43.

One of the oldest records on glioma in China was noted in Lang Ying's Tsi Hsiu Lei Kao, written in the beginning of the 16th century. The writer adds another case report to the Chinese literature. The present case is unique in that the patient underwent operation earlier in the course of the disease and was followed up longer than occurred in any other cases known in this country. It was in a Shantung girl, seven years of age. (References.)

China Medical Journal.

Delbes, P. Veil's juxtachoroidal galvanocauterization in retinal detachment. Ann. d'Ocul., 1945, v. 178, March, pp. 110-121.

Simple galvanocautery with very fine needles was used successfully in five or six patients. The detachment and tear were drawn on a transparent sheet containing an outline of the fundus. This was used as a guide during the operation with ophthalmoscopic verification. Punctures should be only deep enough to appear as faint fundus dots with the ophthalmoscope. The detachment is first delimited peripherally with a number of punctures. A smaller circle of punctures is placed about the tear. If ophthalmoscopic examination is not possible, the circle must be somewhat larger. The last few punctures are made deep to permit escape of the subretinal fluid.

Max Hirschfelder.

Goldsmith, J. Periarteritis nodosa with involvement of the choroidal and retinal arteries. Amer. Jour. Ophth., 1946, v. 29, April, pp. 435-446. (13 figures, references.)

Koch, F. L. P. Retinal vascular micrometry and essential hypertension. Arch. of Ophth., 1945, v. 34, Oct., pp. 321-334.

The methods employed in the measurement of retinal blood vessels are reviewed in detail. The arteries in the vicinity of the nerve head in normal persons are found to range in caliber from 50 to 120 μ when measured with the heliometer. The anatomy and physiology of the arterial vessels of the retina are discussed.

The development of various theories of hypertensive vascular disease is given. The author quotes his measure-

ments, along with those of others, of the mean caliber of retinal arterioles in the four groups of hypertension. The classifications of Keith and Wagener and of Volhard are used. The review is so comprehensive that it cannot be easily abstracted. John C. Long.

Kraus, A. C. Provisual red and visual red. *Amer. Jour. of Physiol.*, 1946, v. 145, Feb., p. 561.

From the bovine retina provisual red and visual red were isolated. Visual red was prepared directly from provisual red and from the residue obtained in the preparation of the provisual red. Both substances are a red, viscous, amorphous lipid. They are soluble in acetone, ether, chloroform, and glacial acetic acid, are insoluble in water, and do not crystallize. The provisual red is soluble in alcohol; the visual red is fairly soluble in absolute alcohol, but almost insoluble in 85 percent aqueous ethyl alcohol.

Absorption spectra of the provisual red in absolute alcohol begin at 540 $\mu\mu$ and are maximal at 440 $\mu\mu$ and 330 $\mu\mu$. Visual red with antimony trichloride in chloroform gave a bluish-purple color with a maximal spectral absorption at 480 $\mu\mu$. Preliminary analytic data for the determination of the molecular structure of these substances are reported. R. Grunfeld.

Kurz, O. The problem of retinal cysts. *Ophthalmologica*, 1944, v. 107, May-June, pp. 233-255.

Four cases of retinal cyst are discussed. Two of them were observed in connection with retinal detachment. The retina tore near the ora serrata, and large cysts were formed next to the area of tearing. In both cases there was also a cyst in the macular area which could not be seen with ordinary oph-

thalmoscopy, even when a red-free filter was used. Only slitlamp observation with the use of a special contact glass brought out the true character of the macular lesion. In one of these eyes satisfactory surgery was not followed by good vision. The retina of young people with retinal detachment which is characterized by ruptures at the ora serrata and which has a tendency to cyst formation should be examined with the slitlamp. Kurz also describes two patients who had retinal cysts in the periphery of the fundus without retinal detachment. One of these patients had an idiopathic cyst without any symptoms, the other had signs of a healed chorioretinitis in a myopic eye. The inflammatory process was held responsible for the cyst formation due to nutritional disturbances in the retina. The theories involved in the question of the formation of retinal cysts are discussed. Cystoid degeneration of retinal tissue with rarification of cyst walls can lead to information of large cysts, but there are also certain hypertrophic processes, especially in young individuals, through which larger cysts become surrounded with connective tissue. Max Hirschfelder.

Lee, F. M. Intraocular parasitism. *West China Med. Bull.*, 1945, v. 2, June 15, p. 52.

There are few reports on the invasion of the interior of the eye by parasites. Two cases were encountered by the writer in the hospital. In one eye the worm was seen in the anterior chamber, which soon disappeared into the vitreous. In both instances there were general leucocytosis, eosinophilia and an increased sedimentation rate. Unfortunately, the worms were not identified. (References.)

China Medical Journal.

Malling, A. A case of pseudonephritic retinitis. *Acta. Ophth.*, 1942, v. 20, pt. 1, pp. 63-68.

The writer reports a case of optic neuritis in a man 33 years of age, whose vision in the left eye was rapidly reduced to perception of hand movements. There were papilledema of three diopters, fine hemorrhages on the disc, and a temporal hemianopsia. Two weeks later he developed a stellate figure in the macula, with isolated peripapillary hemorrhages—a picture resembling angiospastic neuroretinitis. The general examination, including spinal puncture and X-ray studies of the skull, were negative.

The possible pathologic processes which could explain the fundus picture are an optic neuritis close to the chiasm extending forward to the optic disc, a toxic lesion simultaneously involving the optic nerve and retina, and a central retinitis secondary to the optic neuritis.

Manschot, W. A. Synchysis scintillans. *Acta Ophth.*, 1942, v. 20, pt. 1, pp. 80-90.

A detailed report of a microscopic and chemical examination of the vitreous from an eye with primary synchysis scintillans. The findings confirmed the former observations that the scintillating vitreous bodies consist of calcium soaps. (6 illustrations.)

Ray K. Daily.

Porsaa, Kaj. Acute spontaneous and postoperative hypotony in retinal detachment. *Acta. Ophth.*, 1942, v. 20, pts. 3-4, p. 379.

The literature is reviewed with tabulation of the spontaneous and postoperative cases, and three cases are reported. They are cases of retinal detachment in high myopia, in which an

acute hypotony developed. In two of the eyes there was severe pain and injection. In all three the anterior chamber was deep, the aqueous cloudy, the iris green, and there were opacities in the vitreous. In two eyes there was also a green discoloration of the sclera. From a study of the reported histologic data the author concludes that the direct cause of the hypotony is a lesion in the choroid, and that acute hypotony occurs when in addition to the retinal tear there is a concomitant perforation of the choroid which permits free passage of fluid from the vitreous into the suprachoroidal space. Hemorrhages from the choroidal lesion could explain the greenish color of the iris and sclera, the cloudiness of the aqueous and the vitreous opacities. Detachment of the ciliary body, which had been found histologically in some cases might be the cause of the pain and irritation of the eyes. The occurrence of acute hypotony postoperatively in retinal detachment is an unfavorable prognostic sign. The author suggests that in places where the sclera is thin, particularly in myopic eyes, diathermy be applied with a weak current and fine electrodes, in order to avoid damaging the already stretched choroid and sclera.

Ray K. Daily.

Roe, Oluf. Blindness after loss of blood. *Acta Ophth.*, 1942, v. 20, pt. 1, pp. 48-54.

A man, 66 years of age, developed visual disturbances after a hemorrhage caused by a duodenal ulcer. The right eye was totally blind and the left eye had a loss of the lower half of the visual field, with a normal central visual acuity. From a review of the literature, the author concludes that the visual loss is caused by ischemia, acidosis, and illumination. The acidosis, which

reduces the buffer capacity of the cells, probably occurs more readily in patients in a poor general condition, and it is in such patients that visual disturbances are apt to occur. The increased glycolysis in the retina produced by illumination contributes to cell injury by adding to the hydrogen-ion concentration. The increased exposure to light as the patient recovers from shock may account for the onset of the visual disturbance a few days after the hemorrhage, when the general condition of the patient is improving. Patients with anemia after loss of blood should have their eyes protected from light, and the study of the pupillary reactions as a part of a routine examination should be avoided.

Ray K. Daily.

Streiff, E. B. Retinal circulatory abnormalities in the carotid-sinus syndrome. *Presse Méd.*, 1945, No. 39, Sept. 29, p. 522.

Streiff reviews the literature on the carotid-sinus syndrome and the relationship of the carotid sinus to the retinal circulation. He points out that in the normal individual, excitation of the carotid sinus (maneuver of Tschermak) provokes a bradycardia and a small drop in systemic and retinal arterial pressure without subjective sensations. In contrast, under the influence of pathologic factors, such as atherosomatous changes in the carotids or the sinus, tumors of the neck region, and goiter, the reactivity of the carotid sinus is markedly increased. Light compression then produces a considerable bradycardia and a strong drop in arterial pressure. There follows a series of subjective and objective difficulties which characterize the carotid syndrome and "carotid convulsion." Patients suffering from this syndrome complain of visual difficulties, includ-

ing foggy vision and the sensation of a black veil over the sight. This sensation appears to coincide with a marked drop in retinal arterial pressure.

The author refers to a patient, reported by Marcel, who had thrombosis of the central retinal vein. The blood pressure was normal but there was an arteriosclerosis and a hyperexcitability of the carotid sinuses. Streiff also reports a patient who had a macular edema with loss in vision and hyperactive sinus, and a patient with arteriosclerosis who had attacks of mental foginess followed by sudden loss in vision of the left eye; several weeks later the other eye developed an embolus of the central artery with loss in vision; the hyperactivity of the carotid sinus was a prominent feature. The author also mentions the patient of Kouretas and Djacos who had carotid-sinus overactivity and developed attacks of failing vision leading to total blindness.

Streiff mentions the possibility that in cases of so-called spasm of the central artery of the retina, hypotension induced by carotid-sinus activity may play an important role. He thinks that in the same way it is possible that thrombosis of the central retinal vein may be provoked by a drop in retinal arterial pressure. Carotid-sinus hyperactivity must be considered a major cause of retinal arterial hypotension. He concludes by stating that excitation of the sinus, according to the intensity of the pathologic reflex reactions, the state of the vessel walls in the brain and eye, and the degree of stasis in the capillaries and veins, can provoke a simple vertigo, a syncope, a stroke, and, from the ocular point of view, foggy vision, transient blindness, or severe retinal lesions.

Phillips Thygeson.

Suellmann, H. The glycolysis of glucose and fructose in the retina. *Ophthalmologica*, 1943, v. 106, Nov.-Dec., pp. 301-311.

The retina contains ferments which bring about glycolysis of carbohydrates. The isolated bovine retina produces anaerobically about a quarter as much lactic acid from fructose as from glucose. Increased fructose concentrations did not change this relationship, and lactic acid is formed from glucose even in the presence of high fructose concentration. The aerobic formation of lactic acid is greater than the anaerobic. However less lactose is produced from fructose than from glucose. The experiments showed no evidence for the supposition that the relatively small formation of lactic acid from fructose is due to a lesser permeability of the retina for this hexose.

Max Hirschfelder.

Wagener, H. P. Retinal lesions in acute disseminate lupus erythematosus. *Amer. Jour. Med. Sci.*, 1946, v. 211, Feb., p. 240.

The author reviews the literature and notes that in acute disseminate lupus erythematosus characteristic retinal lesions are found. They vary, however, according to the type of the systemic disease, in which vascular, inflammatory, toxic, or embolic features may predominate.

In the vascular type one finds papilledema with extension of the edema into and beneath the retina, retinal detachment and atrophy, guttate retinitis, perivascular exudates and hemorrhages, and choroidal degeneration. The hemorrhages and the soft fluffy exudates are perivascular and, like the papilledema, are due to transudation of fluid and not to intraocular pressure.

In generalized toxemia there may be small, fluffy, yellowish-white or white

spots in the superficial layers of the retina, usually in the posterior part of the fundus and very similar in appearance to the cotton-wool patches of hypertensive retinopathy. On histologic examination they were found to be areas of cytooid bodies. There also were small superficial hemorrhages in the retina which were not related to the white patches nor to the larger retinal vessels and slight papilledema.

In the inflammatory "septic choroiditis," round, white, elevated lesions resembling tubercles of the choroid were found.

In a patient with the embolic type, a bilateral secondary optic atrophy was found. The retinal veins were extremely narrow. Periarterial sheathing was present. Scattered throughout the posterior part of the fundus were numerous discrete punched-out areas of retinal atrophy bordered by a fringe of pigment and always near a retinal vessel. Histologic examination revealed atrophy and gliosis of the optic nerves and atrophy of the walls of the larger arterioles in the retina, with constriction of the lumen and degeneration of the media. In some places extensive perivascular fibrosis was present and produced discrete areas of retinal atrophy.

R. Grunfeld.

Weber, Ernst. Biomicroscopic investigation of the anterior limitations of the vitreous and its connections with the lens. *Klin. M. f. Augenh.*, 1942, v. 108, Nov.-Dec., p. 710.

The author describes the anterior limiting structures of the vitreous as they are seen in biomicroscopy. His studies confirm histologic findings of Wiegiers (1883). The hyaloid, which is essentially a condensation of the vitreous where this structure is in contact with the retina, becomes a free membrane of considerable stability in the

region of the ora serrata. Following the terminology introduced by Vogt, it is here called the vitreous lamella and is easily distinguished from the zonular fibers as it crosses over the posterior surface of the lens and becomes attached to its capsule 1 mm. from the edge. At the site of the attachment the membrane becomes slightly thickened and forms a ring which is ophthalmoscopically demonstrable just inside the maximally dilated pupil. Inside this ring the tissue of the vitreous lamella becomes more delicate and is called the plicata, which is identical with the anterior limiting membrane of the vitreous. Although it is almost indistinguishable from the vitreous structure in the senile and myopic eye, it can usually be identified in young healthy eyes. It is extremely variable in form and structure and readily swirls in extreme convolutions during slight movement of the eyeball. It comes to rest behind a small retrolental space when the eyeball and lids are quiet. These structures are most easily seen in the lower quadrant, but can also be demonstrated in the horizontal diameter by changing the beam of the slitlamp to its horizontal position. OPTIC NERVE AND TOXIC AMBLYOPIAS

Ector, L., and Bégaux-van Boven, C. Glaucoma and papilledema. *Ophthalmologica*, 1944, v. 108, Sept., pp. 113-120.

The factors which play a part in the development of papilledema are an increase of the pressure of the cerebrospinal fluid, increase of the pressure in the intracranial veins, increase in the arterial pressure, decrease of the osmotic pressure of the blood, and decrease of the intraocular pressure. The authors observed a case of bilateral papilledema due to meningeal tumor. During the course of observation the patient developed glaucoma in one eye. The papilledema promptly disappeared in this eye but continued in the fellow eye. Max Hirschfelder.

Pacheco Luna, R. Blindness caused by therapeutic doses of quinine. *Arch. de la Asoc. para evitar la Ceguera en Mexico*, 1945, v. 3, p. 97.

This rare condition has been encountered only three times by the author in the decidedly malarial country of Guatemala. He believes, however, that less severe ocular disturbances caused by quinine therapy, may occur and remain unperceived by the general practitioner. In the author's three cases the symptoms suggest that retinal damage occurred because the patient was sensitive to therapeutic doses of quinine, rather than poisoned by large doses, such as are given in criminal abortion. When ocular disturbances occur during the course of antimalarial treatment, it is advisable to stop quinine at once and substitute atabrine and plasmoquine. One should also begin energetic vasodilation, with acetylcholin or amyl nitrite, followed by vitamin A. This course of medication is indicated even when central vision is greatly reduced and the visual field much contracted. When all treatment has been in vain, sympathectomy has given surprising results on a few occasions.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.

904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. John H. Acheson, New York, New York, died January 18, 1946, aged 70 years.

Dr. Waid E. Carson, Pittsburgh, Pennsylvania, died April 10, 1946, aged 69 years.

Dr. Eugene E. Holt, Jr., Portland, Maine, died February 2, 1946, aged 60 years.

SOCIETIES

At the March dinner meeting the members of the Cleveland Ophthalmological Club were the guests of the ophthalmological department of the Cleveland Clinic. Dr. A. D. Ruedemann, chief ophthalmologist, with his associates, Drs. Kennedy, Mathieson, and O'Connor, presented a most interesting and instructive clinical program.

At the April dinner meeting, Cleveland ophthalmologists who had recently returned from military service were the guests of Dr. Paul Motto, club president. Speakers who described their experiences in ophthalmology in the Army and Navy were: Dr. W. P. Chamberlain, Jr., Dr. W. H. Evans, Dr. R. J. Kennedy, Dr. J. E. L. Keyes, Dr. George King, Dr. Irwin Stolz, and Dr. Benjamin Wolpaw.

The Milwaukee Oto-Ophthalmic Society held its regular meeting on April 23d. Dr. Douglas Buchanan, University of Chicago, presented a paper, entitled "Ocular manifestations of intracranial tumors in children and adults."

Among the speakers at the 1946 session of the Louisiana State Medical Society, held May 6th to 8th, was Dr. Francis W. Raggio, Jr., who spoke on "The management of common eye injuries in the general practitioner's office."

At the eighty-seventh session of the Kansas Medical Society, April 22d to 25th, Dr. H. Rommel Hildreth discussed "Tear-sac surgery."

The 106th meeting of the Illinois State Medical Society was held May 14th to 16th at the Palmer House, Chicago. Among the speakers were: Dr. Paul Carelli, Chicago, "Relation of near-point convergence to squint surgery;" Drs. Watson Gailey and George E. Morgan, Bloomington, "The surgical management of squints;" Dr. H. S. Sugar, Chicago, and Harvey J. Forestner, D.D.S., Chicago, "Methacrylic-resin implant for sunken upper lid following enucleation;" Dr. Helen Holt, Chicago, "Ocular observations in deficient diets;" Dr. Samuel J. Myers, Chicago, "Diagnosis and treatment of

blepharoptosis;" Dr. Edmund B. Spaeth, Philadelphia, "The Marcus Gunn jaw phenomenon;" Dr. Thomas D. Allen, Chicago, "Pan-American Ophthalmological Congress in Montevideo;" Dr. Oscar B. Nugent, Chicago, "Cataract extraction by the vacuum method;" Dr. Kenneth L. Roper, Chicago, "Lancaster's technique of cataract extraction," and Dr. Bertha A. Klien, Chicago, "The eyegrounds in the differential diagnosis of arterial hypertension."

MISCELLANEOUS

The Eye Bank for Sight Restoration, Inc., recently announced the awarding of seven scholarships to ophthalmologists for training in the technique of the corneal-grafting operation, and the establishment of two fellowships to carry on research in blindness resulting from corneal damage. The ophthalmologists who received the scholarships are all trained eye surgeons, certified members of the American Board of Ophthalmology, recognized in their field, and veterans of the past war. They will receive their training at the Corneal Research Laboratory, located at the headquarters of the Eye Bank at 210 East 64th Street, New York. (See page 746.)

The doctors who received the awards are:

Dr. John A. Cetner, assistant attending ophthalmologist at the Albany, New York, Hospital, and instructor in ophthalmology at the Albany Medical College.

Dr. Fred Sauter, chief refractionist at the Brooklyn Eye and Ear Hospital.

Dr. Henry L. Birge, who specialized in eye work at the Mayo Clinic.

Dr. Maurice Croll, a captain in the Army, chief of the eye, ear, nose and throat departments of various station hospitals.

Dr. Milo H. Fritz, a major in the Army, now stationed at the Valley Forge General Hospital at Phoenixville, Pennsylvania, and who, after discharge, will become a member of the Dartmouth Medical School's department of ophthalmology.

Dr. Earl H. Merz, a captain in the Army, stationed at the Valley Forge General Hospital.

Dr. Alston Callahan, a former Army captain, who has just been appointed to the chair of ophthalmology at the University of Alabama Medical College in Birmingham.

Of the two scholarships, one was established from the funds of the Eye Bank. It was awarded to the New York University Medical

School, to be used by Dr Donald Hughson of the Bellevue Hospital's department of ophthalmology, under the direction of Dr. Daniel Kirby, professor of ophthalmology, for experimental work in corneal grafting.

The other, a fellowship of \$2,650, given by the Milbank Memorial Fund to the Eye Bank for the study of the vascularization of the cornea, has not yet been awarded.

BOOKS—WAR VICTIMS

During the war, the libraries of half the world were destroyed in the fires of battle and in the fires of hate and fanaticism. Where they were spared physical damage, they were impoverished by isolation. There is an urgent need—now—for the printed materials which are basic to the reconstruction of devastated areas and which can help to remove the intellectual blackout of Europe and the Orient.

There is need for a pooling of resources, for coordinated action, in order that the devastated libraries of the world may be restocked as far as possible with needed American publications. The American Book Center for War Devastated Libraries, Inc., has come into being to meet this need. It is a program that is born of the combined interests of library and educational organizations, of government agencies, and of many other official and nonofficial bodies in the United States.

The American Book Center is collecting and is shipping abroad scholarly books and periodicals which will be useful in research and necessary in the physical, economic, social and industrial rehabilitation and reconstruction of Europe and the Far East.

The Center cannot purchase books and periodicals; it must depend upon gifts from individuals, institutions, and organizations. Each state will be organized to participate in the program through the leadership of a state chairman. Other chairmen will organize interest

in the principal subject fields. Coöperation with these leaders or direct individual contributions are welcomed.

What is needed. Shipping facilities are precious and demand that all materials be carefully selected. Emphasis is placed upon publications issued during the past decade, upon scholarly books which are important contributions to their fields, upon periodicals (even incomplete volumes) of significance, upon fiction and nonfiction of distinction. All subjects—history, the social science, music, fine arts, literature, and especially the sciences and Technologies—are wanted.

What is not needed. Textbooks, out-dated monographs, recreational reading, books for children and young people, light fiction, materials of purely local interest, popular magazines such as *Time*, *Life*, *National Geographic*, etc., popular nonfiction of little enduring significance such as Gunther's *Inside Europe*, Haliburton's *Royal Road to Romance*, etc. Only carefully selected federal and local documents are needed, and donors are requested to write directly to the Center with regard to specific documents.

How to ship. All shipments should be sent prepaid via the cheapest means of transportation to The American Book Center, c/o The Library of Congress, Washington 25, D.C. Although the Center hopes that donors will assume the costs of transportation of their materials to Washington, when this is not possible reimbursement will be made upon notification by card or letter of the amount due. *The Center cannot accept material which is sent collect.* Reimbursement cannot be made for packing or other charges beyond actual transportation. When possible, periodicals should be tied together by volume. It will be helpful if missing issues are noted on incomplete volumes.

K. R. Shaffer, Executive-director

FIG. 8 (VAIL). FUNDUS OF THE RIGHT EYE TWO MONTHS AFTER OPERATION

THE SCLERAL-RESECTION (EYEBALL-SHORTENING) OPERATION*

DERRICK VAIL, M.D.

Chicago

Before developing the thesis of this address, I should like to try to express my gratitude and humble thanks for the very great honor of being invited to give the de Schweinitz Lecture in the year of victory over our enemies and before this distinguished group of friends and colleagues. I have never approached a task with more diffidence and humility than I have this present one. How can one adequately pay tribute to the many-sided man whose name this lectureship bears? How can one sufficiently express his appreciation for this genius of our time, whose qualities, talents, and kindly influence live in our thoughts and deeds, whose monument is everywhere in our libraries, in our daily work, and in our hearts? There is no one who deserves more respect and admiration than this man of kind manners, the ophthalmic surgeon of exquisite delicacy, the master of neatness and tidiness in his work, the leader of ethical practice, the beloved preceptor of notable pupils, and the author of numerous and living contributions of note to our science. Those of us fortunate to have known him, be it ever so slightly, will always recall with deep affection the figure and charm of his princely person, his personality, his strong character, his help, and his skill, and above all, his

polite and courteous attention to our own individual problems that we brought or sent to him, never in vain and never without profit to our patients and to ourselves.

But the debt that I owe him is still more personal. Out of the pages of his writings, his wisdom has guided me and has solved many problems for me during these war years of great responsibilities in an unfamiliar assignment. I should like to take this opportunity to speak for a few moments of the medical officer, Brigadier General George E. de Schweinitz, Chief Consultant in Ophthalmology to the Surgeon General during the first World War. His writings and reports on ophthalmology contained in the History of the Medical Department in the World War, published by the War Department in 1924, were the first things I sought out on entering the Army and were ever at hand for reference.

On October 11, 1917, the then Lieutenant Colonel G. E. de Schweinitz, M.R.C., received confidential orders No. 92, W.D. par. 10, requesting him to proceed overseas on an inspection trip to study the problems of ophthalmology in the Medical Corps and to report his findings and recommendations to the Surgeon General. In the company of several other officers in the Office of the Surgeon General, he left on October 29, 1917, and returned on March 1, 1918. Col. Allan Greenwood, M.R.C.,⁴ the Senior Consultant in Ophthalmology to the Chief

* The de Schweinitz Lecture. Delivered before the Section on Ophthalmology of the College of Physicians, Philadelphia, November 15, 1945. From the Department of Ophthalmology, Northwestern University Medical School.

Surgeon, A. E. F., in his "History of ophthalmology in the A. E. F.," published in the same volume, pays this tribute: "Before the arrival of a large number of American troops in France a most helpful and important stimulation toward an improvement in the ophthalmic service in the A. E. F. came about through the observation visit to France and England of several officers from the Office of the Surgeon General. The encouragement given to the young men and the recommendations to the Chief Surgeon and the Surgeon General as a result of this visit were the real start of the Ophthalmic Service of the A. E. F." I can add with truthfulness "and were the real start of the Ophthalmic Service of the E. T. O.," as I hope to show you.

Lieutenant Colonel de Schweinitz, before seeing the American units, visited and observed the British Eye Service in France, both at the front and at the base. He was impressed with the efficiency with which the eye patients were handled, particularly with the speed with which prescriptions for spectacles were filled, often within 15 minutes, even in the front lines. He studied the British methods and equipment, found much to praise, and detected some flaws there which he endeavored to correct in our own Service. His recommendations, although not entirely carried out, resulted in an Ophthalmic Service in the A. E. F. that was second to none. Had his original recommendations been followed to the letter at the time of our preparation for war in 1940 or even as late as 1941, much of our troubles and many of the problems that we later encountered in the E. T. O. and other theaters would have been avoided. But I think that the War Department suffers a chronic form of Korsakoff's syndrome, particularly a loss of memory for the lessons of recent wars. In this instance, at any rate, it forgot the ophthal-

mic experiences of the last war and muddled into the same errors, fortunately not entirely too late for correction in the E. T. O.; very late, however, for the M. T. O., and almost too late for the Pacific Theater.

Colonel de Schweinitz recommended that one ophthalmic surgeon be stationed in each evacuation hospital. In this war it was not done until the lessons of the African Campaign had been bitterly learned. By the time the Table of Organization of an Evacuation Hospital, which is a front-line establishment, had been officially changed to include an ophthalmic medical officer, there was a grave shortage of officers. It was another example of "too little and too late." One had to be content with what could be scraped up, and the ophthalmic care of the wounded soldier in the Army areas was, perhaps, not so good as it might have been. There was no provision for the placement of an enlisted man trained as a practical optician in an evacuation hospital. Our officers searched their detachments and generally came up with an optometrist or optician whom they wangled into helping them in the eye clinic.

Colonel de Schweinitz recommended, too, that optical shops be established not only in the base of the eye centers but also in the forward areas. These optical shops were to be equipped with round frames and stocked with preground round lenses that only required edging for speedy insertion. Our system of issuing oval lenses and fancy frames, together with round gas-mask insert lenses—in other words, two types of lenses—was a clumsy one and led to many difficulties. After several years of bitter frustration the situation was eased, but never became entirely satisfactory in any theater of operation. The development of auxiliary or portable optical repair units was slow and late. But I must say that

those that arrived were well used. This is a lesson we could have learned early from Dr. de Schweinitz's report.

Among his recommendations was one advising the encouragement of ophthalmic research. It was fruitful in the last war. It has influenced the policy along this line in this one, and the results of this encouragement are now apparent in our journals.

His most important recommendation was that of placing a chief consultant in Ophthalmology in the Chief Surgeon's Office. It is a matter of history now how valuable this was in the last war, and it is written for all to see. It could have been read in 1940. In this war, no authorization for such a position was ever made. In the E. T. O. the consultants in the medical and surgical specialties were appointed at the specific request of General Paul Hawley, the Chief Surgeon, and charged against the allotment of officers on his staff. No other theater of operations had these consultants. In the Mediterranean Theater the Chief Surgeon was compelled by circumstance to utilize the services of Major Trygve Gundersen (MC), in this capacity and on an informal basis. Without the recognition that should go with the importance of the post or the grade the position required, Major Gundersen did a splendid job and cleaned up a mess for which he has received little credit and no promotion. No consultant in ophthalmology was appointed in the Pacific Area until a few weeks before V-J Day, when Lt. Col. James Greear (MC) was chosen. He was about to sail when victory was won. There were many ophthalmic problems in that theater crying for solution up to the very end. Nor was it until the spring of 1944 that a Chief Consultant in Ophthalmology, Major Elliott Randolph (MC), was appointed to the Office of the Surgeon General. From the beginning

of the prewar preparations in 1940 until then, ophthalmic policies and plans were kicked around more or less haphazardly in the Office of the Surgeon General and referred to medical officers who were not ophthalmologists nor in some cases particularly interested. Major (now Lt. Col.) Randolph's appointment was a great success and he handled very efficiently the ophthalmic problems that came up.

Colonel de Schweinitz reported on the lack of equipment, particularly perimeters. The Supply Division of the Army Medical Department is allergic to perimeters and the lack of equipment is a perennial cause of complaint. Very few perimeters or slitlamps were provided the overseas units in this war either.

The results of Dr. de Schweinitz's report became apparent in early 1918. A Chief Consultant (Colonel Greenwood) was appointed to the staff of the Chief Surgeon, A. E. F., the equipment improved, base optical shops and auxiliary optical shops were developed, and eye centers established which functioned well and capably.

The reading and studying of this report was of inestimable value to me in my capacity as Senior Consultant in Ophthalmology in the E. T. O. The hints, clues, and specific recommendations guided me at a time when no other source of help was available. The ophthalmic services in the E. T. O. were improved accordingly. So you can see why my personal gratitude to the guiding hand of George E. de Schweinitz, as revealed in the pages of a book, is most profound.

His chapter on "Ophthalmology in the United States" in the same volume is a masterpiece of assembling and presentation. Those of you who have read it will recall the eloquence of the writing, the same policies of treatment, the orderly arrangement of text and illustration, and

the valuable and lively descriptions of specific cases of war injuries. Increase the number of cases and alter the statistics upward, and the chapter would give us the ophthalmic lessons of this war. The historical and prophetic sense exhibited here is another side of Dr. de Schweinitz's genius that should, some day, be further explored to the great benefit of our profession.

Therefore, if I have succeeded in this exposition in picturing to you and calling to mind but a small part of the enormous contribution that Dr. de Schweinitz has made in the field of war ophthalmology alone, my debt to his memory will have been partially discharged.

I have been much tempted to devote this lecture to a review and discussion of the work done by Dr. de Schweinitz in the last war and continue the parallel description of ophthalmic matters and policies in this one. I am quite sure that the honors would remain with Dr. de Schweinitz and his group in spite of the fact that this war was a much greater venture. I am also quite certain that the ophthalmic care of the sick and wounded was better in this war than in the last, but only because of the better professional training of the ophthalmic medical officers as a group compared with the ones in the last war, and in spite of more or less muddled planning.

However, I think that we are all fed up for the time being with war topics and discussions of military matters and war medicine. Perhaps later on our appetite for these subjects will return. I, for one, would, therefore, prefer to discuss a small subject in the field of ophthalmic surgery. It is one, I think, that would have interested Dr. de Schweinitz were he here today, for one of the facets of his many-sided character was his keenness for and skill in all aspects of surgery pertaining to the eye.

HISTORY OF SCLERAL RESECTION

Scleral resection was introduced in 1903 by Leopold Müller¹⁰ of Vienna and was originally designed for retinal detachment in patients with myopia, usually of high grade. Müller considered that the cause of the retinal detachment in these cases lay in a stretching of the sclera at the expense of the retina. It logically followed, therefore, that he should try to shorten the globe and thus bring the sclera to the retina. It is not clear from reading his description just how he expected the retina to stay in place, for nowhere do we find him discussing adhesive choroiditis.

He selected for operation those cases of detachment that had persisted for a year or more without improvement. In his early cases he performed the Krönlein operation in order to expose the temporal aspect of the eyeball, choosing this area arbitrarily because of its relatively easy access. In answer to a question raised in a discussion of the operation as to why he chose the temporal part of the eyeball and not the area of the greatest detachment, Müller said that he performed the operation only when the entire retina was detached. He later abandoned the Krönlein operation, replacing this step by an external canthotomy.

His first patient was operated upon in 1903. The case was that of a man with myopia of 9 diopters in his only useful eye. Retinal detachment occurred and was treated medically for some time, without success. After doing a Krönlein operation and a tenotomy of the superior, external, and inferior recti muscles and exposing the operative field of the eyeball, Müller resected an oval piece of sclera 8 to 10 mm. in width and 18 to 20 mm. long from the temporal side of the eyeball. The patient was operated on under general anesthesia; subsequent authors referred to

it as lengthy and formidable. The anterior border of the resected area was 1 to 2 mm. behind the insertions of the muscles, and the posterior border was in the neighborhood of the equator. The postoperative recovery was uneventful, and the case was considered a success in that the vision was restored to ability to count fingers at 3 meters, the retina was back in place, and the periphery of the field of vision was full. The poor vision was due to a central scotoma as the result of old chorioretinitis.

Three other cases were mentioned by Müller at this time, but the details were not given. Although the exact technique that Müller followed is not described in his original presentation, one can gather a very good idea from a study of subsequent papers by various authors, especially one by Lenz.⁷ Silk sutures were placed prior to excision and tied as the operation proceeded. Müller writes of the care that is needed to avoid injuring or rupturing the choroid as it is exposed, and of the danger of serious hemorrhage and loss of vitreous. With a fine knife, he punctured the choroid as it lay exposed, thus releasing subretinal fluid and permitting the choroid to be tucked in as the sutures were tied.

In 1913, Müller¹¹ reported two cases of retinal detachment cured by scleral excision and mentioned that he had done the operation on 19 patients.

Between 1903 and 30 years later, when Lindner⁵ revived interest in the operation, there appeared sporadic case reports and articles in the literature, all of which were European. The interesting thing to me in the study of these reports is the paucity of details regarding the operative technique itself or the results, which on the whole were not good. Dr. Leopold¹² of Philadelphia, in discussing a recent paper by Pischel, remarked that he had collected 121 cases of scleral resection

from the literature, in 25 of which there was successful reattachment and in 31 of which partial or temporary reattachment; the rest presumably were failures. This represents cures of about 20 percent, which, considering the types of cases in which the operation is usually performed, is, to my mind, brilliant.

As is well known, Lindner in 1933 modified Müller's technique. He reported operating 23 times on 12 eyes which, with few exceptions, were associated with myopia. He thought that the best results were to be obtained in those cases in which he removed a piece of sclera from the entire circumference of the eyeball in two operations, or in those cases wherein the detachment of the retina occurred in aphakic eyes.

The technique described by Lindner was used for the first time in this country by D. K. Pischel.¹³ He and Miller reported the successful case in detail and gave a full analysis of the technique which I should like to quote here.

The sclera is laid bare, and one rectus muscle is cut off. Specially equipped dividers are needed, one leg of which has a dull point and the other a sharp blade. A line concentric with the limbus and 9 to 10 mm. from it is lightly cut in the sclera by drawing the dividers over it, the blunt end being kept on the limbus and the blade end in the sclera. Next, a second line is cut posterior to the first one, in a similar manner, the blunt end of the compass being kept on the first cut and a new cut being made with the blade end. These two incisions should be from 2 to 6 mm. apart.

The incisions are deepened with a keratome through three quarters of the scleral thickness. Care must be taken not to perforate the sclera and choroid, as the eyeball may collapse or a severe hemorrhage may occur. Double armed fine chromic catgut sutures are placed 2 mm. apart through both peripheral lips of the incisions (in the form of a mattress suture), leaving the flap free. These sutures should be placed at this time for it is difficult, if not impossible, to do so after the piece of sclera has been entirely excised. After the sutures are in place, the crescent of sclera is slowly cut out. First, the two parallel incisions are joined at one end, and then with a fine scissors the remaining layers of scleral fibers at this end are cut through

leaving the choroid bare. Care must be exercised to see that the choroid is free from the sclera. When 2 to 3 mm. have been cut through, the first set of sutures is carefully tied, care being taken that the choroid is not caught in the lips of the sclera as the sutures are drawn up. The free end of the flap of sclera is drawn under the other sutures and the flap is cut through farther along, the sutures again being tied as more choroid is laid bare. As the process continues and the globe becomes smaller, the choroid will be bulged out through the incision by the pressure from within. The choroid must be punctured with a fine discission needle and some of the intraocular fluid be allowed to escape. [Borley¹ in one of his papers mentions the value of repeated paracentesis during the operation at this stage in order to prevent too rapid and too much herniation of the choroid.] The choroid can then be tucked back inside the sclera. In making the puncture one should avoid large choroidal vessels, as otherwise disturbing hemorrhage may occur. After the crescent of sclera has been completely excised and the last scleral suture tied, the cut muscle may be re-sutured, and the conjunctival incision closed. In cases in which former operations had been performed, the choroid will be found adherent to the sclera. Here a thin layer of scleral tissue may be left behind.

In his most recent paper, Pischel¹² enlarges on the technique and mentions that it is advisable to touch the choroid, at least where punctures are to be made, with a 3-percent potassium-hydroxide solution, and wash off any excess. He goes on further to say:

Experience has shown several points worthy of emphasis. When operating too soon after previous surgery, the sclera will be found to be boggy. Sutures pull out easily and an unexpected scleral perforation can occur. In re-operated areas, adhesions of Tenon's capsule to the sclera are very troublesome, and cause considerable bleeding which must be controlled. Here, also, care must be taken not to cut into the sclera when dissecting blindly. Vortex veins may interfere with the desired placement of the lines of incision and necessitate varying the symmetry of these. Sometimes a thin layer of scleral tissue in which vortex veins are imbedded can be left and folded inward, as in choroido-scleral scars. Cutting such a vein exteriorly causes hemorrhage difficult to control, but cutting it internally may cause devastating intraocular hemorrhage.

He discusses the difficulties and dangers

of the operation and continues on to give valuable hints on how to avoid them. This article is most noteworthy, for it not only presents the technique of the operation and case reports by an author of experience, but the description is followed by a most enlightening discussion. It should be read in its entirety by all who are interested in the subject.

RECENT AND PERSONAL CASE REPORTS

Scleral resection has been employed successfully in (a) cases of retinal detachment, (b) cases of high myopia, and (c) cases of scleral staphyloma with and without retinal detachment.

RETINAL DETACHMENT. The recent literature, since Lindner's article appeared in 1933, is not rich in case reports and studies, although it is entirely possible that the operation has been performed more often than reported. For example, in 1940 I performed a scleral resection on a woman whose only eye was aphakic and on whom two previous diathermy operations had been done without success. The retina was reattached, and the corrected vision restored to 20/70. In 1941, as a last resort, the operation of scleral resection was done three times on the only eye of a young man who had a complete detachment but no real improvement followed, although the eye stood the operations surprisingly well. These cases were not reported at the time because it was desired to accumulate more cases and experience before presenting the material. This is very likely the experience of other surgeons.* Pischel¹²

* Since the preparation of this paper it was learned that Dr. D. W. Bogart of New York presented a paper before the New York Society for Clinical Ophthalmology, on October 1, 1945, discussing the surgery and his results on 18 cases of scleral resection for retinal detachment. He very kindly sent me notes of his paper, which has not yet been published. His operation

and Borley² have each reported their results in a small series of cases, and the record, on the whole, is good when one considers the desperate nature of the cases chosen. For example, there is the brilliant result obtained by Pischel in his second case, which I should like to cite in full detail. It emphasizes the premise that one should not give up in retinal surgery until all is hopelessly lost. Pischel's dogged determination and the patient's fortitude brought about an astounding cure.

A young man, aged 30, had had congenital cataracts needled innumerable times. The right eye was finally lost. A last operation on the left eye, apparently pulling out a dense membrane, gave him about 10/200 vision with ability to read typewritten copy with a magnifier. In July, 1940, he was sent to me (Pischel) because of a retinal detachment in the nasal superior quadrant. Briefly, examination showed an aphakic eye, eccentric pupil, moderate oscillatory nystagmus, and a detachment of the retina in the nasal superior quadrant. It was necessary to give avertin anesthesia to stop the nystagmus so that a reasonably complete fundus examination could be made. A small doubtful tear was seen toward 10 o'clock.

The first operation was a Lindner undermining, with the result that the detachment spread to the whole nasal half. The second operation was a diathermy coagulation of the original region. This resulted in spread of the detachment to include the entire lower half as well.

consisted, briefly, of the excision of a piece of sclera 5 by 12 or 14 mm. near the equator in the area of the detachment. A specially designed caliper was utilized to mark off the area. The incision down to the choroid was made with a specially designed knife. Following the closing of the wound, the surface over the area operated upon was "coagulated" by using a suitable spatula heated in an alcohol lamp. Eighteen eyes were operated upon; 39 percent were cured; 39 percent showed 80-percent cure; 15 percent showed from 25- to 40-percent cure; and one out of 18 was a failure. In other words, 78 percent of these 18 eyes showed from 80- to 100-percent cure. Ten of the 18 eyes were aphakic. It is to be noted that all 18 eyes were considered inoperable by the usual methods. Ten of them had had previous operations, and three had had as many as three operations.

The third operation, undertaken too soon, resulted in an unexpected perforation through the boggy sclera, with a gush of watery brown fluid, allowing the eye to collapse. The fourth operation, undertaken two months later, was an eyeball shortening of the whole lower half of the globe, a 3 mm. wide crescent being cut out. At the same time the site of the tear was again treated with diathermy coagulation. Convalescence was uneventful. Ten days post-operatively the patient stated that he saw better. Two weeks later a fundus examination showed the retina everywhere to be less elevated. Conditions improved and the patient finally recovered 6/200 vision with the retina everywhere in place. The visual field was normal. This condition prevails . . . over four years later.

I believe that there is not enough statistical data in the literature as yet to give us more help than we already have. The cases prior to 1930 ought to be discarded in such a study, because the modern knowledge of the surgical treatment of retinal detachment began at about that time. Lindner's paper (1933) focused our attention on the main principles of scleral resection, and the relatively few cases reported by him, Pischel, Borley, and others since that date are suggestive and promising only. One cannot praise these pioneers too highly. I wish, therefore, to emphasize the point that scleral resection is an operation that is feasible and offers some hope of success, even in extreme instances. There are many problems that still need to be ironed out. For example, we need to know more about what happens to an eye after scleral resection. Animal experiments offer a fertile field for study here. Technical details will improve and new instruments will be devised that will help shorten what is now an arduous and long operation.

HIGH (MALIGNANT) MYOPIA. A paper by W. E. Borley and O. R. Tanner¹ in a recent issue of the American Journal of Ophthalmology had for its title "The use of scleral resection in high myopia." This, so far as I know, is the first time

that such a title has appeared in the literature. The authors mention that Müller, Elschmig, Lindner, and Pischel have reported cases. Hildesheimer⁵ also reported attempts made by Arlt, Wolfe, Perinaud, and Galezowski to relieve high myopia and to improve or to prevent retinal detachments in myopic eyes by scleral resection. Holth⁶ did what he called "Trepanato sclerae prae-aequatorialis" in two cases of high myopia in which no retinal detachment existed, claiming good results although he mentioned few details and gave no report on vision. In four cases (two with retinal detachment) of high myopia, the myopia decreased from 12.0 to 5.50 diopters, 17.0 to 6.0 diopters, 16.0 to 10.0 diopters, and 18.0 to 5.50 diopters. His operation consisted, briefly, of using a 2.5-mm. Bowman trephine to bore a hole in the sclera to the choroid, about 12 mm. from the limbus between the external and inferior recti muscles. He then used his 2-mm. scleral punch, after first passing a spatula between sclera and choroid, backward in a meridional direction, and removed a piece of sclera 1.8 by 1.5 mm.

In 1937, Hildesheimer, using an electrocautery in the form of a loop, excised a piece of sclera for the reduction of myopia in two cases of unilateral high myopia, with good result and with a reduction in myopia in the first case from 31.0 to 20.0 diopters, and in the second from 15.0 to 13 diopters.

Borley and Tanner's case was that of a woman of 56 years. Prior to operation her refraction was: Right vision with $-17.75D.$ sph. $\approx -1.0D.$ cyl. ax. 80° was 15/200; left vision with $-18.75D.$ sph. sufficed for the perception of hand movements at two feet. The eyeballs were protruberant, and there were extensive choroidal changes and vitreous opacities, especially in the left eye. In January, 1941, the left eye was operated upon and a strip of sclera 2 mm. wide, 11 mm.

from the limbus from the 12- to the 6-o'clock position, was excised. The technique used was that previously described, with the addition of repeated paracenteses at about 5-minute intervals to allow the intraocular pressure to remain low. The postoperative course was uneventful. The same operation was performed on the right eye in June, 1941. There was slight but definite improvement up to January, 1943. In September, 1944, the corrected vision was: R.E., 15/70; L.E., finger counting at two feet. There was no change in the refraction, which is difficult to explain, and no change in the ocular fundi except for the heavily pigmented scar of the operation far temporally.

Pischel (1945) reported the case of a man, aged 55 years, with myopia of 17 diopters, whose vision in the right eye was 20/50; left eye, finger counting at three feet. A scleral resection was done on the left eye as a "training" move. Later, the same operation was performed on the good eye, a 3-mm. crescent of sclera being excised from the temporal half. The anterior chamber was repeatedly drained during the operations. Convalescence was uneventful. The author states that the distance vision changed little but the near vision improved. The change, if any, in the refractive error was not mentioned.

It is disappointing that here, too, more details are not given in these case reports. However, we do learn from them that the operation is possible and not particularly dangerous. Further studies will be stimulated. I believe that the operation does have a future in selected cases and it appears, on the surface at any rate, to be less hazardous to the eye than is the removal of a clear lens in these cases of high myopia.

SCLERAL STAPHYLOMA. 1. *The anterior (intercalary) scleral staphyloma.* In 1943 Gayer Morgan¹⁴ showed a patient before

the Ophthalmological Society of the United Kingdom upon whom he had successfully performed an excision of a ciliary staphyloma. The case was that of a young boy who had developed a ciliary staphyloma of the right eye, five years after glaucoma secondary to a needling operation for congenital cataract had developed. The conjunctiva was dissected off the posterior half of the staphyloma, conjunctival sutures were inserted and left loose. Mattress sutures were passed right through the staphyloma from the limbus to the healthy sclerotic behind the staphyloma by means of a large cutting surgical needle. It had been planned to evacuate a little fluid from the staphyloma, but enough escaped through the holes made by the needle, and the eye became reasonably soft. The sutures were then tied, and the staphyloma was snipped off. The preoperative astigmatism of 6 diopters was reduced to about 1 diopter. One attack of glaucoma had subsequently occurred, but the intraocular pressure was controlled by eserine. This successful case is a most impressive one, and the technique described is simple. The operation should be performed in all such cases which otherwise are hopeless and end in enucleation or perforation.

Although not quite in the same category, the case described by Spaeth¹⁵ might be mentioned here. A limbal staphyloma or ectasia followed a blow with a screw driver. The conjunctiva above the staphyloma was incised in a crescentic manner and mobilized for a large subsequent flap. The staphyloma was then opened with sharp scissors, and the iris prolapse was cleanly removed with de Wecker scissors. Two 6-0 waxed black-silk sutures were inserted in the edge of the corneal lip and passed into the bared scleral lip of the original corneoscleral incision, tied, and cut short. The conjunctival flap was then brought

over and sutured slightly past the midline of the cornea.

2. *Equatorial scleral staphyloma.* Before the American Ophthalmological Society in 1940, I reported¹⁶ a case of equatorial scleral staphyloma and retinal detachment cured by excision. The patient was a white woman, 57 years of age, who, on June 16, 1936, noticed a blur in the vision of the left eye which rapidly became worse. The right eye was normal. The examination showed a balloon detachment of the retina in the upper temporal area. When the overlying sclera was exposed in preparation for a diathermy operation, a large equatorial scleral staphyloma was unexpectedly encountered (fig. 1). It measured, roughly, 12 by 15 mm. and began abruptly at a point 6 or 7 mm. from the limbus. It occupied the area between the tendons of the superior and external recti muscles and, therefore, was obviously over the retinal balloon. Because of this situation, it was decided to excise the staphyloma in a method similar to the eyeball-shortening operation described by Lindner. In view of the subsequent events, I should like to describe the operation which was performed on June 29, 1936, in the exact words used in the case report. Two double-armed sutures were inserted along the edges of the staphyloma (fig. 2) and looped out of the way. A fixation suture was placed in the center of the ectasia. A Graefe-knife incision was made along the upper and inferior edges, and excision was completed with curved scissors (fig. 3). The fixation suture was of incalculable value at this point, for traction on it gave excellent control of the eyeball and of the portion being excised and, at the same time, created a negative pressure which prevented vitreous from spilling. Subretinal fluid and presumably fluid vitreous were lost, but, on completion of the excision, which included part of the retina, the main vitreous body could be

seen glistening clearly like water deep in a well. The sutures were quickly tied and a third was placed between them (fig. 4), thus bringing the edges of the wound tightly together and forming a small linear ridge of sclera.

The eye healed kindly, the retina was

sph. $\approx +1.75D$. cyl. ax. 115° , prior to the detachment, to $+1.75D$. sph. $\approx +5.25D$. cyl. ax. 25° , three years after operation.

The patient's son-in-law, who is a well-trained and keen ophthalmologist now in the Army, kept me informed from time

Figs. 1-4 (Vail). The scleral-resection operation. Fig. 1, Diagrammatic appearance and position of the staphyloma. Fig. 2, Showing the value of the fixation suture. Fig. 3, Diagrammatic drawing of position of sutures. Fig. 4, Showing closure of the wounds.

reattached, and, when the patient was examined three years later in preparation for the report of the case, the vision with correction was 20/40+ and J2 (fig. 5). The line of vision was "tented," owing to a slight disturbance in the macula. The refraction had changed from $-1.0D$.

to time regarding the condition of her eye, which remained good.

On April 28, 1945, she appeared at the Army hospital in which her son-in-law was stationed, complaining of a blur in the vision of the right eye. The following notes were made from his examination.

"The right eye has been observed at approximately yearly intervals since 1936, and since 1939 there has apparently been a very slow stretching of the sclera in the temporal area, as evidenced by some chorioretinal pigmentation in the temporal portion of the fundus. This was very slight until June, 1944, when a considerable amount of chorioretinal scarring was observed. The fundus temporally was seen with a minus 13.00 sphere lens, while the macular area was seen with a minus 1.00 sphere lens. It was felt that the stretching of the congenitally thin sclera in the left eye had been rather rapid prior to the detachment of the retina in the left eye in 1936. The sclera in the right eye had probably been stretching very slowly, giving the chorioretinal adhesions an opportunity to form and hold the retina in place. In the first week in April, 1945, the patient bumped the top of her head on a cabinet door. Visual symptoms began about the 17th or 18th of April as a small defect in the upper nasal field of the right eye. It became more noticeable, and in a few days she found that she was unable to read with the right eye. The examination on April 28th showed a large bullous detachment in the lower temporal quadrant; the vision was reduced to counting fingers at 2 feet.

External Examination, Right eye. Between the 8- and 10-o'clock positions, about 12 to 15 mm. from the limbus, the sclera was very thin and ectatic. This was greatest between the 9- and 11-o'clock positions. It extended back as far as one could see. The cornea was clear, the anterior chamber of normal depth, the iris pattern normal, and the pupil was round and reacted.

Left eye. Between the 2- and 4-o'clock positions, about 10 mm. from the limbus, there was a healed scar in the conjunctiva and sclera, the site of the

operation. At the lower end of this scar there was a small, ectatic, slightly bluish area due to the distortion of the scleral coat. This was essentially the same as it was in 1936.

Ophthalmoscopic Examination, Right eye. The nervehead was normal. The retina between the 12- and 5-o'clock positions was in place, and no particular degenerative change was noted. From the

Fig. 5 (Vail). Fundus appearance three years after operation; left eye.

5- to the 10-o'clock position there was a detachment of the retina extending from the equator to the periphery. From the 5- to 6-o'clock positions, from the equator to the periphery, there was a slightly wrinkled, low detachment which joined a large bullous detachment. Above the upper temporal border of the bulla there was a flat detachment which extended to about the 11-o'clock position. At the 9:30-o'clock position, between the equator and the ora, there was a small area of blood in the retina. No definite hole or tear could be made out. Toward the periphery the elevation of the retina was less marked than at the equator. The macular

area was obscured by the bullous detachment (fig. 6).

Left eye. There were a few stringy vitreous opacities centrally located. The nervehead and blood vessels were normal. A slight irregularity of the surface of the retina was observed in the macular area. The retina everywhere was in place. There was a large scar in the equatorial region extending from the 2- to the 4-

Under local anesthesia (retrobulbar and Van Lint injections of novocaine) and superior rectus bridle suture, the conjunctiva and Tenon's capsule were incised over the area of the scleral staphyloma, which was discovered to be larger than suspected, measuring approximately 20 by 7 mm. and rising abruptly from the surface of the sclera. It was bluish in color and very thin, dimpling at the

Figs. 6, 7 (Vail). Field studies. Fig. 6, Preoperative field of vision; right eye. Fig. 7, Postoperative (6 weeks) field of vision; right eye.

o'clock position. The retinal vessels could be seen to stop abruptly at the chorioretinal scarring. Peripheral to the operative site there was considerable chorioretinal scarring, and the retinal vessels could not be seen. There was no other fundus lesion.

The patient was kept in bed, wearing pinhole glasses and using atropine in the right eye. On May 8, 1945 (V-E Day), operation on the right eye was performed (scleral resection) by me, assisted by Lt. Col. Elliott Randolph (MC.), and Capt. John McGavic (M.C.). I am greatly indebted to them for the opportunity and their skillful help during the operation, and for the careful notes and postoperative care of the patient by one of them (J. McG.).

slightest pressure. The external rectus was reflected. Three 7-0, black-silk sutures on atraumatic needles were firmly placed in the sclera on each side of the ectasia, in which a fixation suture had been placed. A part of the ectasia was then excised in the same way as described in the operation on the left eye, and the three silk sutures were tied. This left a buckled area in the sclera at the lower end of the incision. It was felt that reattachment of the retina was quite unlikely to take place if this folding of the remaining scleral ectasia was allowed to remain. Sutures were then placed in the sclera on each side of the fold, and the rest of the staphyloma resected. When the sutures were tied, the contour of the globe was quite good, and no buckling or fold-

ing remained. During the short time that the scleral wound was open, the vitreous appeared to be of good consistency. Surprisingly little vitreous was lost. The conjunctiva and Tenon's capsule were closed with interrupted black-silk sutures. A good reflex was present after the operation. Atropine and sulfathiazole ointment were applied, and a binocular Ring mask used.

The piece of excised sclera was thin and rather "brittle." Some blood and pigment were present on its inner surface, but no retinal elements were to be seen on microscopic examination of the tissue later.

Convalescence was uneventful. In 12 days the postoperative reaction, which was not great, had almost completely subsided. There was a good fundus reflex throughout. Some blood in the lower portion of the vitreous was seen, as well as choroidal and retinal hemorrhages at the lower end of the incision. The retina appeared to be in place. The field of vision was full (fingers). On the 24th of May, pigmentation along the lips of the scleral-incision area within the eye could be seen. The patient was discharged from the hospital on June 10 (fig. 7). On July 8, 1945, two months after the operation, the examination showed the retina to be in place everywhere. A small vitreous hemorrhage was still present. The retinal and choroidal hemorrhage had become absorbed, and pigmentation along the scar was well advanced (fig. 8, see Frontispiece).

The refraction in the right eye was found to have changed from $-0.50D.$ sph. $\approx -0.75D.$ cyl. ax. 175° with which the patient had $20/20+$ vision prior to the onset of the detachment, to $+1.25D.$ sph. $\approx +4.50D.$ cyl. ax. 175° , which gave her a vision of $20/30+1$. With $+2.50D.$ sph. added she read J1. The vision of the left eye on this date,

with $+3.50D.$ sph. $\approx +3.25D.$ cyl. ax. 25° was $20/40-1$; with a $+2.50D.$ sph. added she read J1 slowly.

This extraordinary case of double, scleral equatorial staphyloma and detached retina cured by scleral resection of the staphyloma gives us much food for thought. The origins of these lesions are mysterious, and they are usually monocular when they do occur. The underlying weakness of the sclera may very likely persist for a long time before the sclera more or less rapidly yields. The absence of all signs of glaucoma in this case rules out increased intraocular pressure as the exciting cause. It is logical to assume that some inherent weakness of the scleral coat existed, probably on a congenital basis, perhaps similar in its genesis to that encountered in keratoconus, affecting the temporal equatorial region of both eyes. The possibility that a cyst of the retina may be the cause of the scleral ectasia as the result of pressure is another thought. If this were so, it would explain the absence of retinal elements on the underlying surface of the excised specimen. Nor is there any answer to the question: Why was vitreous lost at all if the retina was intact? The more or less linear scar seen with the ophthalmoscope, particularly in the left eye, suggests a linear cut or tear in the retina at the time of operation. Other questions that need an answer are: Why was the temporal area affected in each eye? Is this the influence of the action of the superior oblique or other ocular muscles upon a weakened sclera? Nine years have elapsed since the first operation was performed and, as yet, no recurrence of the staphyloma has developed in spite of the continued normal action of the superior oblique and other ocular muscles. The temporal radial meridian of the eyeball is greater than the nasal in relation to the support given to the eyeball by

the optic nerve and the limbal area, and this may also be a factor. But further speculation is fruitless until we know more about the condition. However, I believe it would be a wise policy to excise these staphylomas before retinal detachment occurs in view of the fact that the technique of scleral resection lends itself very well to this condition.

OTHER CONDITIONS in which scleral resection could be considered (speculative only): 1. The removal of a melanoma of the choroid in an only eye. 2. An area of severe episcleritis, or inflammatory nodule, or malignant lesion in the sclera. 3. The excision of disintegrating areas or plaques in the sclera in scleromalacia perforans.

EXPERIMENTAL STUDIES

So far as could be determined the only laboratory experimental studies of scleral resection reported in the literature are contained in a paper by Wiener.¹⁷ He, however, was primarily interested in resecting strips of sclera longitudinally, thus lengthening the eyeball. He found that if one excises an elliptical segment of sclera 9 mm. long and 1.5 mm. wide from four opposite sides of the eye and brings the edges together by means of three sutures each, the eye will be length-

ened approximately 2.5 mm. to 3.0 mm. The refraction is changed from about normal to between 8 and 9 diopters minus. Wiener found that in lengthening the eye, the increase is 1.27 times the width of one of the segments removed. In shortening the eye, the decrease is 0.636 times the width of the segment removed, or about half as much as in the lengthening process.

SUMMARY AND CONCLUSIONS

The technique of scleral excision is described. It has been successfully performed by a number of ophthalmic surgeons in cases of retinal detachment, high myopia, and anterior and posterior scleral staphylomas. Enough operations on each of these conditions have been performed to indicate its value in selected instances. It is worthy of further study, particularly with a view to improvement in its technique and the development of special instruments to increase the facility of its function. There is a need, too, for experimental studies, particularly in laboratory animals. The question of scleral staphyloma needs further elucidation.

I am indebted to Lee Allen, artist, Department of Ophthalmology, University of Iowa Medical School, for the beautiful fundus painting.

RETINAL HEMORRHAGE AS SEEN IN AN ATOMIC-BOMB CASUALTY

KARL B. BENKWITH, M.D.

Montgomery, Alabama

The writer was recently stationed in Japan as Force Surgeon on the staff of Marine General Ray Robinson, the Commanding General of the Fukuoka Occupation Force. We were the first troops to arrive and assume occupation control of Northern Kyushu and Southern Honshu, Japan, early in September, 1945. Located in Fukuoka was the Kyushu Imperial University and its medical school, which hospitalized many atomic-bomb patients from both Hiroshima and Nagasaki.

Through the courtesy of Drs. Tamura and Ikui, who directed the Ophthalmic Institute of the Kyushu Imperial University, the illustrations for the case here-with reported were made available.

The patient was a Japanese girl, aged 14 years, showing retinal hemorrhages as a result of the atomic-bomb explosion at Nagasaki, Kyushu, Japan, on August 9th.

The salient fact was that this patient suffered from excessive gamma-ray ir-

radiations, which produced her clinical picture. She was first observed early in

Fig. 1 (Benkwith). The patient on October 10, 1945. Recent symptoms were petechiae in the skin, slight epilation, bleeding from the gums, and blurred vision.

September when an American-Japanese medical investigation team proceeded to Nagasaki to appraise the effects of the "bomb" on a cross section of the Nagasaki population. She was discovered to be ambulatory, although she had earlier suffered from malaise, headache, fever, nausea, and diarrhea. It was later (fig. 1) that she noted petechiae in her skin, slight epilation, bleeding from the gums, and blurred vision.

She was hospitalized for observation at the Ophthalmic Institute, Kyushu Imperial University at Fukuoka, where initial blood studies showed a leucopenia of 2,200 white blood corpuscles, prolonged bleeding time, decrease of platelets, and an anemia of 2.2 million red blood cells. She showed no evidence of blast wounds, cuts, or burns. She was approximately one mile from the accepted hypo-center of the atomic-bomb explosion, in her home, which was demolished at that time.

Examination of the fundi early in September showed a similar picture in each eye; that is, one of massive preretinal hemorrhages and hemorrhages into the fiber layer of the retina (fig. 2). These hemorrhages were distributed about the discs and in close association with the retinal vessels for approximately three disc diameters peripheral to the discs. In

the macula of the left eye was a large sausage-shaped hemorrhage appearing to be fed by the terminal arterioles and venules of that region. Small, fluffy, white exudates, were scattered about the disc and in close approximation to the retinal vessels of greater caliber.

During hospitalization the patient remained ambulatory and received little specific medication except iron, persimmon-leaf extract, plus the Japanese diet of rice, vegetables, and tea. The ill effects of the excessive radiant energy on this patient gradually subsided, so that by November there was a definite clearing of the fundi. The retinal hemorrhages were absorbed faster than the whitish areas of apparent serofibrinous exudate, which also disappeared. Very little evidence of pathologic change was visible in the fundi by December. However, in the fundus of the left eye a small white, although more discolored, area persisted. This is shown in the drawing to lie just inferior to the macular region. The vitreous was clear of floaters, and the vision returned to normal. The patient's general physical condition showed improvement which coincided with the improved ocular findings. She was pronounced well and recovered at the turn of the year.

400 Norman Bridge Road (6)

FIG. 2 (BENKWITH). FUNDUS OF THE LEFT EYE, SHOWING MASSIVE PRERETINAL HEMORRHAGES AND HEMORRHAGES INTO THE FIBER LAYER OF THE RETINA. A LARGE SAUSAGE-SHAPED HEMORRHAGE APPEARS TO BE FED BY THE TERMINAL ARTERIOLES AND VENULES OF THAT REGION. SMALL, FLUFFY, WHITE EXUDATES ARE SCATTERED ABOUT THE DISC AND IN CLOSE APPROXIMATION TO THE RETINAL VESSELS OF GREATER CALIBER.

SOME EFFECTS OF VITAMIN-A DEFICIENCY ON THE EYE OF THE RABBIT*

IDA MANN, A. PIRIE, K. TANSLEY, AND C. WOOD
WITH THE TECHNICAL ASSISTANCE OF M. BARNETT

Oxford, England

It is well known that nutritional or deficiency disease is responsible for widespread disorders of sight. The Report on Nutrition in the Colonial Empire (1939) states that "... diseases due to deficiency of vitamin A are perhaps the most common of all in the Colonial Empire. There are reports from a wide selection of territories of affections of the eye, nightblindness, xerophthalmia, keratomalacia . . . the prevalence of Bitot's spots and xerosis of the skin and hair are probably also due to insufficiency of vitamin A." This report has been supported by D. F. Moore (1940), who states that in the Philippines half the children attending hospitals had xerophthalmia, that in the Dutch East Indies, 4,000 children in half a million were blind, and that this high incidence is attributed to xerophthalmia.

Although much work has been done on the subject since the discovery of accessory food factors by Hopkins (1912), there are still certain gaps in our knowledge of the effects of vitamin-A deficiency on the eye. It is well known that the most striking general change in both man and experimental animals is a metaplasia of the surface cells of epithelia in the direction of the squamous and keratinized type. The epithelial metaplasia is always in the direction of simplification to a less highly specialized type; for example, mucous membranes lose their mucous cells and become uniform and keratinized. This change tends not to involve the basal cells, so that regeneration is usually possible and rapid. The surface involvement is

widespread, affecting both ectodermal and endodermal epithelia so that many remote and superficially unrelated clinical effects are produced; for example, effects on the eyes, the skin, the lungs, the vagina, many glandular organs, and the central nervous system.

In addition to the fundamental epithelial change, various observers have described effects on the growth of blood vessels (for example vascularization of the cornea, Wolbach and Howe, 1925), effects on the resistance to infection of various organs, pigmentary and bony changes, and changes in nerve fibers. The papers reporting these changes have recently been summarized by Bicknell and Prescott (1942) and by Wolbach and Bessey (1942).

Although the main effects on the eye (nightblindness and xerophthalmia) are known with certainty, there still remain many details that are obscure. In the first place, we are not certain how much of the eye change is primary and directly due to the deficiency and the resulting epithelial change, and how much is secondary, due either to infection or to changes in the lacrimal glands, in bone, or in the nervous system. We do not know precisely the time relationship between the various clinical signs, nor the relation between the level of vitamin A in the blood and the histologic appearances of the eyes. Neither do we know the early biomicroscopic appearances, nor their relation to the histology.

We have, therefore, made a study of the condition in rabbits and have drawn certain conclusions about to be discussed for this species. It must be fully under-

* From the Nuffield Laboratory of Ophthalmology, The Eye Hospital, and The Oxford Nutrition Survey, 10 Parks Road.

stood, however, that a direct argument from rabbits to man is inadmissible in detail for three reasons: (1) The physiologic requirements of rabbits are not identical with those of man, so that the same sequence of similar clinical signs may not hold good for both. (2) Since the conjunctiva of rabbits is not normally exposed to the air, changes characterized by dryness in man may be somewhat different in appearance in rabbits. (3) Since alterations in retinal function cannot at present be detected in rabbits, structural retinal change alone has been considered in this paper, and no conclusions as to nightblindness can be drawn.

Before proceeding to a detailed description of the experiment and the findings, it is advisable to state briefly the conclusions we have arrived at for rabbits. These all confirm Wolbach and Howe's (1925) that the primary action is on epithelium:

1. The primary effect of vitamin-A deficiency on the eye is an epithelial change. This appears first on the cornea and can be detected here with a slitlamp, one to three months before it is visible with the naked eye, and often two to three weeks before it can be diagnosed with certainty by means of a loupe.
2. A pigmentary change in the conjunctiva (of pigmented rabbits) appears simultaneously with, or slightly after, the corneal change and can first be seen with the slitlamp.
3. A surface conjunctival change can be detected with the slitlamp some time later than the pigmentary change.
4. Any changes that there may be in the lacrimal gland are not the cause of the corneal change, which appears first.
5. The substantia propria, the corneal endothelium, and the corneal nerve fibers are not abnormal to slitlamp examination; neither were retinal changes observed with the ophthalmoscope or histologically.
6. Corneal vascularization and infiltration do not occur as part of the deficiency syndrome.
7. Signs of deficiency were usually established with no signs of concomitant infection. In a few cases apparent infection developed later than deficiency signs. This may account for vascularization of the cornea in the rare cases in which this occurs. No bacteriologic examinations were made.
8. The younger the rabbit at the beginning of

the experiment the shorter the time required to produce changes in the eyes.

9. Correlation between plasma vitamin-A levels and time of onset of eye changes shows that the blood level sinks to about 10 percent of the normal before any eye change can be detected.
10. The eye changes described, apart from those produced by gross secondary infection, can be reversed by treatment with vitamin-A, the corneal change disappearing first, before the plasma vitamin-A is normal, and the pigmentation of the conjunctiva last.

EXPERIMENTAL METHODS

Rabbits were used, since they are easily rendered deficient in vitamin A and are docile under repeated slitlamp and other examinations. In addition, they present a larger area of conjunctiva for observation than do rats or guinea pigs and also frequently show limbal pigment rings similar to those seen in Africans and some other pigmented races. Their intraocular structure (for example, depth of anterior chamber) is more similar to that of man than is that of most other convenient laboratory animals.

Sixty rabbits of mixed laboratory stock were used. Fifty were rendered vitamin-A deficient and 10 were litter-mate controls. The rabbits were chosen mainly for eye color. Most were from a crossed Dutch strain with blue or heterochromic irides and a limbal pigment ring. As will be seen later, the stock was not entirely free from congenital abnormalities, one rabbit having a coloboma of the nerve sheath and others showing minor retinal abnormalities. Otherwise the animals were all healthy.

The deficiency was induced in two age groups. The first was composed of healthy weaned rabbits put on a vitamin-A-deficient diet when aged five to seven weeks. There were eight of these. Those in the second group were younger, their nursing does being put on an A-deficient diet as soon after the birth as possible. This diet was continued to the young afterwards, which could, therefore, be

said to have received an A-deficient diet from three to four weeks of age.

DIET

A diet of crushed oats plus 1.5-percent powdered chalk mixed and made just damp with water was fed *ad libitum*. In addition, water was freely available, and 5 mg. ascorbic acid, mixed in a spoonful of bran for convenience of measurement, was given to each rabbit each day.

Percentage analysis of crushed oats (Bull. No. 48, Ministry of Agric. & Fish.)

Protein	Oil	Carbohydrate	CaO	P ₂ O ₅
10.3	4.8	58.2	0.14	0.81

B complex g/100 gm. wet crushed oats (Burkholder, 1943)

B ₁	B ₂	Nicotinic Acid	Biotin	Pantothenic Acid	Pyridoxin	Folic Acid
113	8	75	9	75	3	220

The chalk was added to bring the calcium/phosphorus ratio of the oats near unity in order to diminish the need for vitamin D. Rickets has not been reported in rabbits, and in general no vitamin D was given to the experimental animals;

Chart 1 (Mann *et al.*). Growth curves of three litter mates. No. 39 was fed greens throughout. No. 40 died after eight months on the deficient diet. No. 41 was dosed with vitamin-A concentrate after four months' deficiency.

but some of the young rabbits put on the diet at the age of three weeks were given one or two weekly doses of 200 I.U. irradiated ergosterol. They showed no difference in growth rate nor in the development of vitamin-A deficiency. The grown rabbits ate about 75 gm. (dry) of the diet per day. Controls were given the same food with about two ounces of greens, or a daily dose of about 500 I.U. of vitamin A by mouth. The "A Controls" grew at about the same rate as those receiving greens, reached a normal body weight, and appeared healthy in every way. Attempts to improve the growth rate of rabbits given vitamin A during cure of the

Chart 2 (Mann *et al.*). Growth curves of three litter mates. All were given one dose of about 1,000 I.U. of vitamin A at start of experiment (three weeks old). No. 52 was given vitamin-A concentrate throughout life. No. 50 was on deficient diet for 14 months, and No. 51 was cured with vitamin-A concentrate after 11 months' deficiency.

deficiency by addition of 5-percent casein, or 5-percent dried brewers' yeast to the diet made no noticeable difference. The rabbits were weighed once a week. Charts 1 and 2 show the growth curves of two litters, each having control and experimental animals.

Vitamin A was given by mouth either as Prepalin (Glaxo) or as a solution of vitamin A in arachis oil. The dose was approximately 500-1,000 I.U. per day per rabbit. A large dose was purposely chosen to get rapid cure.

ESTIMATION OF VITAMIN A IN THE BLOOD

Blood was taken before the morning feed from the marginal ear vein into citrated tubes. Three to 5 ml. of plasma was stored in ice overnight and then the carotene and vitamin-A content were estimated by the following method, a modification of that described by Yudkin (1941): 2.0 ml. of the plasma was pipetted into a 15-ml. test tube and 2.0 ml. 95-percent ethyl alcohol added drop by drop, the tube being well shaken after each addition; 4 ml. of petrol ether (B.P. 40° to 60°) was then added, and the tube was well corked and shaken by hand for 10 minutes. The layers were allowed to separate, and 2.0 ml. of the petrol-ether layer was transferred to a colorimeter tube; 0.25 ml. of petrol ether was added, and the carotene measured in a photoelectric colorimeter with a 440-millimicron filter. After the petrol ether had been evaporated off on a waterbath at 55° to 60° and then for a few seconds at 70°, the residue was dissolved in 0.2 ml. of anhydrous chloroform, one drop of acetic anhydride was added, and the tube placed in the colorimeter with the light intensity already adjusted (620 millimicron filter). Then 2.0 ml. of Carr-Price reagent was added to the tube in position from an automatic pipette and the maximum temporarily steady galvanometer de-

flection recorded. The tube was removed at once and the result discarded if the solution was turbid. Galvanometer readings were converted to I.U. carotene and vitamin A per 100 ml. plasma by reference to calibration curves.

The rabbits were inspected frequently, and at least once a week were investigated thoroughly with a slitlamp. As soon as the signs of deficiency had reached the desired stage, one eye of the rabbit was removed (under intravenous nembutal anesthesia) for sectioning. Portions of the conjunctiva, lids, and lacrimal and Harderian glands were taken at the same time. The animal was then treated with vitamin A, and the progress toward cure was observed in the remaining eye. When improvement appeared maximal, the rabbit was killed, and the tissues of the second eye were sectioned.

CLINICAL COURSE OF THE DEFICIENCY

The *first sign* of any effect from the deficient diet was a failure to gain weight at the same rate as the litter-mate control. The second sign was the appearance of a change in the corneal epithelium detectable only with the slitlamp. The lag in weight appeared earlier and was more marked the younger the rabbit at the beginning of the experiment, a fact noticed also by Mellanby (1944), and, similarly, the corneal change appeared earlier in the younger rabbits. At its earliest appearance, this corneal change could best be described as a very superficial epithelial disturbance. A few of the surface cells in the central area of the cornea looked opaque and slightly greasy. Microscopic examination later verified that these were epithelial cells undergoing metaplasia into squamous and keratinized cells. At first only a few cells here and there were affected, but soon they spread uniformly over the whole central area, which then became opaque, but did not in most cases

reach the limbus. There was no green staining with fluorescein, showing that there was no loss of surface. Of the area of metaplasia only the central part stained faintly pink with eosin, indicating that the cells were keratinizing. Picric acid did not stain.

At first the substantia propria could be seen easily through the altered epithelium. It showed no change. Mouriquand, Rollet, and Chaix (1931) made slitlamp observations in A-deficient albino rats and found vascularization, interstitial infiltration, and edema of the substantia propria. Such changes did not appear in our experimental animals, even after long periods on the deficient diet. The nerve fibers were especially observed in some rabbits and did not change in appearance, number, or distribution during the experiment. Sauer (1939) made a histologic study of corneal nerve fibers in A-deficient rats and found that the nerves grow into the metaplasizing corneal epithelium. He concluded that degeneration of the nerve fibers could not be a primary cause of the epithelial change.

Later, the epithelial cells in the central area became white and greasy, or foamy, in appearance and heaped up into a dense plaque, often showing vacuolization. This plaque might disintegrate and be shed, showing for a few days a smooth, clear cornea. A heaped-up plaque would then be formed again. There was no cellular infiltration into the substantia propria.

The squamous change could be seen with the slitlamp to extend beyond the central area, where it was visible to the naked eye. In some cases it extended to the limbus, although the white heaped-up opacity scarcely ever did.

In some cases the movements of the third lid across the eye produced patterns like wave marks on sand in the loose keratinized layer. In no case did an ulcer develop. Plate 3 shows a normal rabbit eye

and a typical example of fairly severe deficiency.

The *second detectable eye change* was an outward migration of the chromatophores of the limbal pigment ring. This appeared simultaneously with, or slightly after, the corneal change. It led to the apparent widening and thinning of the pigment ring and finally to a smoky discoloration of the whole bulbar conjunctiva. It was readily seen with the naked eye and appeared comparable with the discoloration described by Treacher Collins (1930) as occurring in the pigmented races in man and in vitamin-A deficient animals. That it was due to migration of preëxisting chromatophores and not to a new development is certain, since only those animals with a pigment ring showed it. In a few of the rabbits one eye had a pigment ring and the other not. In these cases only the pigmented eye became "smoky." In one rabbit there was a gap in the pigment ring at the start, and during the experiment the chromatophores were watched, as they migrated first outward and then laterally from the ends of the gap, so that it finally almost disappeared, becoming nearly uniform with the general smokiness. In one instance only was any migration inward on to the cornea observed. This rabbit, which showed very severe changes in the corneal epithelium, extending right up to the limbus all round, also had a thick conjunctival discharge and may have been infected. The pigment migration on to the cornea had the appearance of an epithelial slide, such as occurs after injury, rather than a diffuse migration, and was not typical of A deficiency.

The *third eye change* to appear was an alteration (keratinization) of the conjunctiva, especially in the lower fornix. That this change, which antedates the corneal change in man, should be the last to show in rabbits is probably due to the

fact that practically no part of the rabbit's conjunctiva is normally exposed to the air. It appeared in rabbits a fortnight to three months after the first detectable corneal change and varied a good deal in intensity.

The white, greasy-looking surface accumulations in rubbing off the cornea and conjunctiva might appear as a thick white discharge. This was by no means always suggestive of infection; unfortunately, no bacteriologic tests could be made to clinch this point, but clinically the presence of coincident signs of inflammation—such as, redness of conjunctiva, swelling, eversion or ulceration of the lids—was taken as evidence of infection and not the presence of a foamy or greasy-white discharge alone. Thus, of six rabbits, four developed a severe ulcerative blepharoconjunctivitis with eversion and crusting of the lid margins. They were all in contact, and the condition occurred within 10 days in them all. In one of them, a slight vascularization at the margin of the cornea took place at the height of the inflammation. A fifth rabbit of this presumed-infected group had slight blepharitis and marginal vascularization, which cleared up during the cure of the A deficiency. Another rabbit also showed during the cure a similar but less-marked inflammation with marginal vascularization. Both inflammation and vessels disappeared rapidly under treatment with penicillin. In most of the rabbits we found no signs of inflammation and have no evidence, therefore, that, infection apart, corneal vascularization, infiltration, or ulceration, or conjunctival congestion is a necessary expression of A deficiency. Johnson (1943) found that treatment of

the eyes with liquid petrolatum and metaphen ophthalmic ointment prevented corneal ulcers in rats with severe xerophthalmia. The effect is probably partly mechanical, the eye being kept lubricated by the ointment, and partly anti-infective.

All the conjunctival changes due directly to the A deficiency were of the same nature as those in the cornea. The occurrence of Bitot's spots (white areas of keratinization) in A-deficient rabbits has been reported by Hetler (1934), and recently Kruse (1941) has suggested that thickening and wrinkling of the conjunctiva may be an early sign in man. He states, however, that this change takes many months of treatment with massive doses of vitamin A to clear up, and, from his description, it is not certain whether a thickening of the surface epithelium or of the subconjunctival tissues is meant. The changes in our rabbits were purely epithelial and cleared up rapidly under treatment.

In some of the rabbits, general changes occurred which were of interest, but which were not especially studied. In some cases these appeared before the eye signs, and no definite time correlation could be obtained between them. The rabbits commonly looked ill and seemed listless, with poor appetites. In some, the head was held tilted, and the rabbit tended to move in circles; in three others, affections of the hind legs, paresis, and attacks of deforming arthritis occurred. A similar arthritis also occurred in one control rabbit receiving vitamin A, and in one stock rabbit in the colony. No pathologic evidence of the exact nature of these was obtained, although the nerves of the leg muscles of two of the A-deficient rabbits showed, on

A

B

sectioning, no sign of present or past degeneration. We wish to thank Prof. J. Z. Young for preparing and reporting on these. One rabbit developed noisy breathing and several developed diarrhea.

Table 1 shows the relation between

there was an apparent worsening of the corneal condition, due to heaping up of the keratinized epithelium by the regenerating basal cells. This initial apparent worsening is very striking and was noticed by May and Wolff (1938) in a

age of rabbit, time on deficient diet, and time of appearance of corneal, pigmentary, and conjunctival changes. General changes are not included.

CLINICAL COURSE OF THE CURE

This was much more rapid than that of the development of the deficiency. During the first few days of treatment

baby of seven months during treatment with cod-liver oil. In most cases, an improvement in the corneal condition was apparent in four days. The squamous cells were shed and did not reappear, and the cornea rapidly returned to normal. Often, large sheets of cast-off surface cells could be seen lying in the lower fornix and disintegrating into a thick, white discharge.

In some cases, the corneas were quite normal within a week of the administration of vitamin A; in others, slight changes could be detected for six weeks; the maximum improvement occurred early in all. As the cornea improved, the conjunctival discharge increased as all the surface cells were shed. In some cases the lining of the meibomian ducts was shed also and could be seen being extruded from their orifices. The pigmentation of the conjunctiva was the last macroscopic change to clear up. This occurred very slowly and seemed to be produced by disappearance of the migrated chromatophores and multiplication of the cells in the original pigment ring. In most cases it was not complete for three or four months, and in one, not for 15 months. It is, however, certain that if the animal is kept alive long enough all the abnormal pigmentation does eventually disappear, the eye becoming absolutely normal in every way.

The general condition also improved rapidly. The animal became lively, and the appetite improved. Structural joint change did not, however, recover, nor did the rabbits complete their growth, if this had been arrested. The rabbits which had received the deficient diet from three to four weeks weighed 3 to 4 pounds only, after prolonged administration of vitamin A. Whether this failure to reach normal size means that the diet was lacking in other factors or that the early arrest of growth permanently affected the skeletal and other structures we cannot be sure. It is, however, certain that the eye changes described are solely due to vitamin-A deficiency, since they were completely reversed by its administration.

HISTOLOGIC METHODS AND FINDINGS METHODS

The eyes, lids, and glands were fixed in Zenker's solution. In order to fix the retina quickly, the eyes were immediately

injected with the fixative down the optic nerve before being immersed in it. Pieces of bulbar conjunctiva, including the ring of pigmented cells round the limbus, were removed and stretched out on a slide and fixed in 10-percent formalin in H_2O . They were flattened between two slides during fixation.

All the material was blocked in paraffin wax. Sections of the cornea were cut tangentially, as advocated by Pullinger (1943). Sections of the conjunctiva were cut transversely to show thickening and keratinization of the epithelium, while unstained flat preparations, to show pigment scattering, were also made by dehydrating, clearing, and mounting the strip of conjunctiva on the slide on which it was originally fixed. For the retinal preparations, parts of the back of the eyeball, including the visual streak (Davis, 1929) of the retina, were cut transversely at 10μ .

Weigert's hematoxylin with eosin or van Gieson's stain was used. Some conjunctival sections were also stained with mucicarmine, others with a safranin picroindigo-carmine stain for keratin, but results with hematoxylin and eosin were more detailed. The retinal sections were stained with hematoxylin and eosin by Feulgen's method and by a modification of the azan method in which the azo-carmine is replaced by carmalum, as used in Wilder's silver method. For this modification the sections were mordanted in 1-percent phosphomolybic instead of phosphotungstic acid.

MICROSCOPIC FINDINGS

Cornea. No histologic change was detectable for about a month after a change was easily visible with the slitlamp. The first detectable histologic change paralleled the appearance of a continuous central area of opaque epithelium.

There is general agreement as to the histologic appearance of the vitamin-A-

deficient cornea, but there has been some argument as to which of the changes observed may be regarded as primarily due to the deficiency

Fig. 1 (Mann *et al.*). Healthy cornea. Tangential section through surface layers of cornea of left eye of Rabbit 15 after 7 days on vitamin A. Staining: Zenker, Hematoxylin and eosin.

and which are merely secondary. All observers (Mori, 1922b; Yudkin and Lambert, 1921; Wolbach and Howe, 1925; Mellanby, 1934; Hetler, 1934) agree that the surface layers of the corneal epithelium become keratinized in all species of laboratory animal examined, including the rabbit, but while Wolbach and Howe believed this to be the primary change, Yudkin and Lambert as well as Mori were of the opinion that the corneal changes are secondary to infection (Yudkin and Lambert) or changes in the lacrimal glands (Mori). These workers were impressed by the fact that changes could be recognized in the conjunctiva while the cornea was still apparently unaffected.

Mori found infiltration and vascularization of the cornea in rats and sometimes

ulceration and perforation. Wolbach and Howe, on the other hand, never found corneal ulceration in rats, although vascularization was common, whereas Hetler reported ulceration of the cornea in a monkey as well as in one eye of a deficient rabbit. In addition, she examined the eyes of deficient rats and guinea pigs, but only mentions corneal vascularization in the monkey.

In our rabbits, the surface layer of the corneal epithelium was always keratinized, but there was little alteration either

Fig. 2 (Mann *et al.*). Mildly deficient cornea of rabbit. Tangential section through cornea of right eye of Rabbit 15 after two months on deficient diet. The outer epithelial cells are unhealthy and in the process of being shed but are not yet keratinized. Compare figure 1 (left eye of same animal after cure). Staining: Zenker, Hematoxylin and eosin.

in the basal layers of the epithelium or in the substantia propria (figs. 2, 3). The number of dividing cells in the basal epithelial layers was slightly increased over the normal amount (cf. Wolbach and Howe, 1925, fig. 3) and there were possibly rather more pyknotic nuclei in the substantia propria. Infiltration was not common; we found polymorphonuclear cells in one animal and a little round-

Lambert (1921) and by Wolbach and Howe (1925). In this animal the deficiency leads to general atrophy of the alveoli and keratinization of the ducts of the gland; in the rabbit we were unable to demonstrate any change at all.

Lacrimal gland. Mori (1922a) described changes in the lacrimal glands of vitamin-A-deficient rats which he re-

Fig. 3 (Mann *et al.*). Severely deficient cornea. Tangential section through surface layers of cornea of Rabbit 6 after 14 months on the deficient diet. The surface is keratinized. Note also mitoses in basal layer of corneal epithelium. Staining: Zenker, Hematoxylin and eosin.

cell infiltration in one or two other corneas.

Lids. Focal lesions with infiltration have been described by Yudkin and Lambert (1921) as an early change in vitamin-A deficiency of the rat, while Mori (1922a) found change in the meibomian glands of this animal, which, however, Wolbach and Howe (1925) declared to be insignificant. In rabbits we found some keratinization of the lining epithelium of the lids, but no other change; the meibomian glands appeared normal.

Harderian gland. The effect of vitamin-A deficiency on the harderian gland of the rat has been studied by Yudkin and

garded as being the most important of all. He believed that, by putting an end to lacrimation, the lacrimal-gland changes were responsible for all the other ocular effects. Yudkin and Lambert (1921) confirmed Mori's findings but stated that the changes described by him may be seen in normal rats. Their paper gives the impression that they did not find the lacrimal gland much affected in the rat. Wolbach and Howe (1925) found atrophy of the tubules and keratinization of the ducts in the glands of A-deficient rats.

We found much the same changes as those described by Mori, Yudkin and Lambert, and Wolbach and Howe in our rabbits. The most marked of these was a loss of granular material from many of

the secreting cells, so that their cytoplasm appeared much less dense than normal. These cells were also swollen, so that the central lumen of the tubules affected tended to be obliterated. The nuclei often appeared normal but they were sometimes pyknotic or even missing altogether. Only some tubules of any given gland were affected, and the proportion remaining normal seemed to bear little relationship to the severity of the deficiency.

epithelium. Mori (1922b) reports the finding of keratohyaline granules in the deficient conjunctiva of the rat (but not in the cornea), and Hetler (1934) in the monkey and in one rabbit eye; she does not mention their presence in any of her deficient rats but says specifically that they were not produced in the guinea pig, Yudkin and Lambert (1921) noticed focal infiltration in the conjunctivas of rats during the early stages of deficiency and,

Fig. 4 (Mann *et al.*). Healthy conjunctiva. Transverse section through lower conjunctiva from left eye of Rabbit 38 after seven days on vitamin A. Staining: Zenker, Hematoxylin and eosin.

Fig. 5 (Mann *et al.*). Deficient conjunctiva. Transverse section through lower conjunctiva from right eye of Rabbit 38 after 2 $\frac{3}{4}$ months on deficient diet. The conjunctiva is much thickened and its surface keratinized. Compare figure 4 (left eye of the same animal after cure). Staining: Zenker, Hematoxylin and eosin.

The end result, even after treatment with vitamin A, was atrophy and fibrosis, although there was always a considerable number of normal tubules left. We confirmed Mori's observation that there are areas in which the tissue appears to be a simple mass of nuclei, but like Yudkin and Lambert, found the same phenomenon in the cured and control specimens.

Conjunctiva. It is generally agreed that vitamin-A deficiency leads to thickening and keratinization of the conjunctival

therefore, concluded that the corneal changes were secondary to infection of the conjunctiva. Treacher Collins (1930) refers to a case in which the conjunctiva of a man suffering from vitamin-A deficiency had no mucous cells.

We found keratinization and great thickening of the conjunctival epithelium with pigment in the cells of the basal layers (figs. 4 and 5). The stroma seemed fairly normal, although not entirely healthy, and there were some pyknotic nuclei. There was slight round-cell infiltration of the stroma in some, but by

no means all of the preparations. No mucous cells could be found in the deficient conjunctivas.

The retina. No changes in the appearance of the fundus have been reported in rabbits as a result of vitamin-A deficiency, and none were seen in these experiments.

Characteristic changes in the structure and staining reactions of the retinas of rats and dogs suffering from vitamin-A deficiency were first reported by Tansley

limbs becomes thin, and the retina tends to break at this point, leaving the outer limbs in contact with the pigment epithelium. Later still, the rods become ragged and unhealthy looking and are separated from each other and the pigment epithelium by large vacuolelike spaces. Johnson describes an even later stage in which the whole outer part of the retina disappears, but this was not seen either by Tansley or by Anderson and Hart.

Fig. 6 (Mann *et al.*). Retinal degeneration. Transverse section through retina of right eye of Rabbit 7, showing small area where the rods and cones together with most of their nuclei have disappeared. The surrounding retina is normal. Staining: Zenker, Hematoxylin and eosin.

(1933, 1936) and later confirmed in rats by Johnson (1939, 1943). Similar changes have recently been described by Anderson and Hart (1943) in the retina of the vitamin-A-deficient horse.

The first effect of this deficiency on the rat retina is a loss of differential staining of the inner and outer limbs of the rods with certain histologic stains. In the normal retina, Mallory's triple stain for connective tissues and its modifications, of which the modified azan technique already described is one, colors the outer limbs yellow and the inner limbs blue; whereas with Feulgen's method the outer limbs become purple and the inner green. In the deficient animal, the outer limb loses its characteristic staining reaction and is much less readily distinguishable from the rest of the rod. At a later stage the junction between inner and outer

The rabbits in these experiments showed no retinal changes that could confidently be attributed to vitamin-A deficiency. In some of the retinas the differential staining of the outer limbs of the rods was rather poor, and in some there was a tendency to split between the inner and outer limbs, particularly in the central areas, but in no case was there any evidence of degeneration in any part of the rod outside the nucleus. Four animals (A7, A8, A9, and A19) had a number of degenerate *nuclei* in their retinas, both among the rod nuclei (outer nuclear layer) and the bipolar cells (inner nuclear layer), but these degenerations were confined to rather small areas in the central retina, and, although in some eyes they were associated with the breaking up of the rods, this was not necessarily the case. In A7 there was a relatively small

area where the whole retina outside the inner nuclear layer had disappeared completely, but the greater part of the retina was perfectly healthy (fig. 6). A8 had a coloboma of the optic-nerve sheath, a recessively inherited defect which is known to occur in rabbits (Koyanagi, 1921).

These degenerative changes are very like a form of retinal degeneration which has been observed by one of us (K. T., unpublished observation) in an inbred stock of albino rats and which was found to be inherited and often associated, possibly fortuitously, with coloboma of the optic-nerve sheath. They cannot be due to the vitamin-A deficiency in these rabbits, since the eyes in which they occurred were either from a control animal (A9) or were not removed until all macroscopic signs of deficiency had disappeared as a result of treatment with vitamin A; whereas several enucleated eyes, showing obvious corneal and conjunctival changes, had perfectly normal retinas. Three of the affected animals were litter mates (A7, A8, and A9) and this suggests that we have here an inherited retinal degeneration similar to that already observed in rats. These particular abnormalities were not present at birth in the rat, but appeared about two months later and gradually progressed during the life of the animal.

The occurrence of retinal abnormalities of this type is not uncommon in inbred rat stocks, and the present observations suggest that this may also be the case in rabbits. It is, therefore, of the first importance to make sure that any retinal degeneration observed never appears in litter mates of the same age before ascribing it to vitamin-A deficiency.

In general, the results of these experiments indicate that vitamin-A-deficient rabbits do not show the retinal changes which occur in rats, dogs, and horses.

PLASMA VITAMIN A

It is of importance in assessing the value of slitlamp examination of the cornea in the early diagnosis of vitamin-A deficiency to know the relation between the blood level of vitamin A and the time of detection of the earliest eye signs. It is well known in man that nightblindness can be demonstrated before conjunctival and corneal changes become visible to the naked eye, yet few estimations of the plasma and carotene levels of vitamin-A-deficient animals appear to have been reported and related to eye signs. Rao (1936) reported that the liver of a vitamin-A-deficient rabbit showing xerophthalmia gave a negative antimonytrichloride test for vitamin A, and L. A. Moore (1939) found a rise in plasma carotene after feeding lucerne to vitamin-A-deficient calves which were nightblind but did not show corneal changes.

In our series of rabbits, the plasma carotene and vitamin A were estimated at irregular intervals, both during the establishment of the deficiency and during its treatment. Little or no plasma carotene was found, for the rabbit converts this rapidly to vitamin A. Briefly, we found that the plasma-vitamin-A values sank to about 10 percent or less of the normal before any sign of deficiency could be observed in the eyes with the slitlamp microscope (table 2). The reestablishment of a normal blood level of vitamin A lagged behind apparently complete cure of the eyes. This is in accord with Lewis *et al.* (1942) who found that, in rats, retinal vitamin A remained high when blood and liver concentrations were reduced and that small doses of vitamin A, given to deficient animals, increased the retinal concentration to normal before there was much change in the blood vitamin A and before any detectable amount was laid down in the liver. Failure of

TABLE 2
RELATION BETWEEN PLASMA VITAMIN A AND EYE SIGNS

Rabbit No.	Plasma A I.U./100 ml.	Eye Signs	Plasma A of Control Litter Mate I.U./100 ml.
1	57	normal	150-177
	10	generalized corneal & conjunctival change	150-177

40	26	slight corneal and conjunctival change	104

dark adaptation in man can occur when the blood vitamin-A level is only slightly below normal, although individual variation makes the normal difficult to assess. The corneal and conjunctival changes that we have been describing must be considered as late changes relative to change in the level of vitamin A in the blood and probably to any change in dark adaptation.

One cannot argue directly from these results that corneal and conjunctival changes in man also will not be microscopically visible until the plasma vitamin-A level has fallen to about 10 percent of its normal value, but one must consider it as a possibility.

SUMMARY

1. Biomicroscopic and histologic

changes in the eyes of vitamin-A-deficient rabbits have been observed and correlated with plasma-vitamin-A levels.

2. Plasma vitamin A was found to drop before any biomicroscopic change was visible.

3. The conclusions of earlier workers that the eye changes are primarily due to an epithelial change in the cornea and conjunctiva are substantiated.

4. Keratinization of the cornea and conjunctiva clears up very rapidly on treatment with vitamin A. Removal of conjunctival pigment and reestablishment of the conjunctival mucous cells takes place more slowly.

It is a pleasure to thank Dr. H. Carleton for his help in preparing the photomicrographs.

THE MANAGEMENT OF INTRAOCULAR FOREIGN BODIES IN MILITARY PRACTICE*

GEORGE M. HAIK, LT. COL. (MC), A.U.S.
New Orleans, Louisiana

Because ophthalmic care is so highly specialized, Army medical authorities found it desirable to designate certain hospitals in each theater of war as ophthalmic centers. The 64th General Hospital* was thus designated in April, 1944, and by successive directives continued to serve in that capacity until V-E Day. When the Hospital was first made the ophthalmic center for its area, it was established at Maddaloni, Italy, 45 miles below Cassino, and received large numbers of casualties during the heavy fighting there, particularly during the breakthrough in May. In August it was moved to Leghorn, 12 miles from Pisa, which the Germans still occupied, and for a month it received casualties directly, since there were no evacuation or field hospitals ahead of it. When the Gothic Line was breached and the Allied troops went forward, the situation again changed, and casualties again passed through evacua-

tion, field, and general hospitals, sometimes not reaching the ophthalmic center at the 64th General Hospital until several days after their injuries had been sustained.

It is my purpose in this paper to summarize the observations made and the treatment employed in the management of intraocular foreign bodies during my service as head of the Ophthalmic Department of the 64th General Hospital. The data and conclusions are based on (1) a number of patients cared for at the 64th General Hospital immediately after being injured, who had received no preliminary treatment; (2) a number of patients cared for soon after being injured who had received treatment at a field or evacuation hospital; and (3) a number of patients cared for after a considerable period of time had elapsed since injury, who had been transported from a long distance, through field, evacuation, or other general hospitals. Total number of cases consisted of 311 eye injuries, with 252 battle casualties, 81 intraocular

* From the 64th General Hospital, Italy (the Louisiana State University unit).

foreign bodies, 14 double perforations of the globe, and a number of intra-corneal, intrascleral, and intraorbital foreign bodies.[†]

In the War Between the States, according to Hughes,¹ injuries to the eye accounted for 0.5 percent of all wounds. In World War I the proportion rose to 5 percent. Detailed statistics on casualties

Fig. 1 (Haik). Case 1. Foreign body (shrapnel) lodged in apex roof of orbit having entered through vertex. Roentgenologic examination at operation with probe *in situ*. Transorbital removal.

for the present war are not yet available for publication, but probably the percentage of injuries of this type will show the same progressive increase noted in all the wars of the last century.

The actual incidence of injuries to the eye is even higher than published statistics indicate, for at least two reasons: In the first place, statistics are usually made up without regard to cerebral injuries with which wounds of the eye are as-

sociated. At the 64th General Hospital, for instance, some 10 percent of the intracranial foreign bodies observed entered through the orbit (fig. 1), the eye being irrevocably damaged in most instances in which the patients survived. In the second place, the incidence of foreign bodies is not always apparent in the immediate tabulation of injuries. It is augmented by the cases in which the injury is not immediately apparent, usually because of the predominance of associated wounds of the face, but becomes evident only by the later development of posterior uveitis. In many cases, of which the following is an example, the foreign body enters the eye without the soldier's knowledge of this phase of his wounds.

Patient 1 was admitted to the Ophthalmic Center at the 64th General Hospital from another general hospital five days after the development of an acute chorioiditis of unknown etiology; several months previously he had been treated for wounds of the face. Examination with the slitlamp revealed a small hole in the iris, and upon roentgenologic examination (fig. 2 a, b) an intraocular foreign body was localized. Its removal resulted in almost immediate subsidence of the uveitis. Incidentally, the case illustrates the importance of roentgenologic examination in every instance of uveitis in young individuals, particularly those who have been in combat, for the demonstration of a possible foreign body (case 2).

OPHTHALMIC SURGERY UNDER WARTIME CONDITIONS

An increasing incidence of injuries of the eye would naturally be expected as warfare becomes increasingly mechanized. On the other hand, in spite of the increase in the number of such injuries, the careful application of modern therapeutic methods gives ground for hope of

[†] Acknowledgment is made to Major Arthur V. Hayes, Gulfport, Mississippi, for invaluable aid in the management of these cases.

a decrease in the number of cases of both absolute and relative ophthalmic disability. The experience of the Ophthalmic Center at the 64th General Hospital supports this hope.

Since foreign bodies furnish one of the major ophthalmic problems of military service, it is fortunate that, even before hostilities commenced, the old concept—an eye containing a foreign body

seem. A devastating inflammation may be the result of such conservatism, as the following case shows:

Patient 2, who was wounded in action by a mortar-shell fragment, reached the 64th General Hospital 14 days later, after passing through an evacuation and then a station hospital. The only previous treatment had been the instillation of at-

Fig. 2. (Haik). Case 2. A, Ring method of localization of foreign body. B, Sweet and ring method of localization.

is potentially lost and must be promptly enucleated—was disappearing. The optimistic concept of other observers that many foreign bodies can be left in the eye without risk has been somewhat slower to disappear, however. With the possible exception of small particles of glass, aluminum, and certain new plastics, which are apparently inert, there is no ground for such optimism. All other foreign bodies, as the result of electrolysis and oxidation, act as irritants, and sooner or later may give rise to a chemical endophthalmitis. Certain special objects induce special varieties of inflammation. Those containing steel and iron, for example, give rise to siderosis bulbi, and objects containing copper give rise to chalcosis.

It is true that the removal of a foreign body from the eye is never unattended by risk. On the other hand, the risk is a calculated one, and is far less, most observers now believe, than that of permitting a foreign body to remain in the eye, however innocent its presence may

ropine twice daily. Examination showed a small metallic foreign body in the lens of the left eye (fig. 3). The lens seemed otherwise undamaged, and the eye showed no hemorrhage and no evidence of an inflammatory reaction. The patient had a severe bronchitis, and for this reason, and because the eye was quiet, no immediate treatment was instituted with respect to the eye. For eight days his course was uneventful. Then he suddenly presented a severe chemical endophthalmitis. Immediate Sweet localization revealed the foreign body lying 2.5 mm. below the horizontal plane, in the midline, 9 mm. behind the center of the cornea. It was removed (the patient under sodium-pentothal anesthesia) with a large magnet supplemented by the cataract knife when the particle had reached the surface of the lens. Postoperative therapy, in addition to the usual local measures, included triple-typhoid vaccine and penicillin. Recovery was stormy, and when the patient was evacuated to the United States, he

had only poor light perception.

Ophthalmic surgery in wartime is attended with many difficulties. There is no branch of medicine that requires greater deliberation and delicacy, and there are fewer qualities more difficult to achieve in the circumstances of war, even in rear areas. In the forward areas, where the majority of injuries are sustained, the first attention is concentrated on saving

Fig. 3 (Haik). Case 3. Sweet method of localizing foreign body; foreign body 16 mm. in length, removal posterior sclerotomy. Visual results 20/30.

life, and other injuries often take precedence of injuries of the eye. Transportation to the rear areas is usually remarkably rapid, but necessarily depends upon the exigencies of combat; there are often unavoidable delays, even in injuries in which good results depend in large measure on prompt specialized treatment, while methods of transportation are often far from desirable.

Other difficulties also exist. The removal of foreign bodies from the eye by magnet is, generally speaking, the simplest method, but the proportion of non-magnetic foreign bodies steadily increased during the war, as aluminum and magnesium alloys were increasingly substituted for brass and steel. Foreign bodies which enter the eye in combat are frequently larger than those seen in civilian practice, and, because of their high explosive origin, they frequently enter with great force and do great structural damage; the degree of explosive force, indeed, is more important than the length

of the laceration through which the body enters the eye. The size of the object, though important, is not necessarily the deciding factor in the end result. At the 64th General Hospital some eyes were enucleated when the size of the object was less than 1 mm. in length, and others were saved when the length was more than 14 mm. (case 3).

The most important consideration in the end results of the surgery of foreign bodies is the condition of the eye when the patient is first seen, which implies that the earlier he is seen the more likely that results will be favorable. Generally speaking, foreign bodies must be removed within 48 hours after entrance, if an advanced chemical endophthalmitis is to be prevented. I have observed cells in the anterior chamber of the eye within an hour after injury, but as a rule, the most devastating inflammatory reaction does not occur for four to six days, as the following case illustrates:

Patient 3 was admitted to the 64th General Hospital six days after his left eye had been injured by shrapnel. When he was seen at an evacuation hospital, soon after the injury, his visual acuity was 20/30. The ophthalmologist there was of the opinion that he had suffered a double perforation of the globe and that the foreign body had entered a few millimeters from the limbus. The roentgenologist believed that the object was extraocular. For five days the soldier's course was uneventful. Then a severe chemical endophthalmitis developed, associated with a hazy cornea and numerous deposits on the posterior corneal surface. The iris was of a sickly green color and the aqueous was fixed. As soon as the patient reached the 64th General Hospital an intraocular foreign body was removed. Postoperative therapy included atropine instillations, foreign-protein therapy, and

sulfadiazine. Vision in the injured eye was 20/200 on discharge (case 4).

Important as is prompt attention to eye injuries, the belief that it is better not to attempt the removal of foreign bodies in forward areas, except in cases of extreme emergency grew steadily throughout the war. The delay in treatment which this policy involved was obviated, when circumstances permitted, by giving patients with such injuries priority in air evacuation. There were at least two good reasons for this policy. In the first place, intraocular hemorrhage, one of the most frequent causes of poor results in ophthalmic surgery, is likely to occur as the result of an initial injury and to be increased as the result of additional movement and manipulations; the length of time that the usual patient remained in an evacuation hospital was not sufficient to overcome this risk. In the second place, neither personnel nor equipment was

likely to be highly specialized in forward areas, and the accurate roentgenologic localization essential for the removal of deep-seated foreign bodies was almost impossible to carry out in front-line hospitals. In one series of 17 cases in which

Fig. 4 (Haik). Case 4. Localization of foreign body by Waters method with lead beads on limbus at the 12-, 3-, 6-, and 9-o'clock positions. a, Patient looking upward. b, Patient looking downward.

foreign bodies were removed at the 64th General Hospital, attempts at removal in forward areas had been unsuccessful in 15, undoubtedly because accurate localization was impossible.

Within the limits of the potential seriousness of intraocular foreign bodies, the results at the Ophthalmic Center of the 64th General Hospital were good. There were some tragic cases of complete blindness, but, as a rule, vision was preserved in the injured eye. It would be less than fair not to emphasize that whatever results were achieved at this center were by no means the achievement of the ophthalmic surgeons alone. For one thing, equipment was excellent. For another, the ophthalmic staff had the singular good fortune to have the coöperation of a competent and interested roentgenologic staff. In addition well-trained and enthusiastic nurses* and enlisted men† provided the

patients with care which compared most favorably with that provided for such patients at the best hospitals in the United States.

The great majority of the intraocular foreign bodies observed at the 64th General Hospital, as an analysis of 81 typical cases shows (table 1), was of direct-combat origin or was combat-connected. Most of the others were sustained in the repair of vehicles, welding, chiseling, and similar activities. It must not be forgotten that a civilian life of sorts goes on behind the lines, and that injuries similar to those encountered in civilian life also occur. Singularly few injuries were due, as Stallard² expressed it, "to the stupidities of fools, who, in spite of warnings, dismantled mines and grenades, threw them about, suffered road injuries, etc."

DIAGNOSTIC CONSIDERATIONS

Preëxamination care. Ideally, all soldiers with injuries of the eye were evacuated lying down and remained thus until the character of their wounds was determined, for the reason, already emphasized, that hemorrhage as well as loss of vitreous is a risk in all injuries of the eye and that the risk is increased many times by voluntary movements and careless handling. Practically, many soldiers not disabled by other wounds were received sitting up or even walking.

On admission to the Hospital, any patient with a suspected wound of the eye, regardless of its type, was immediately placed on a litter. He was moved very gently and was cautioned to keep both eyes closed, as if asleep, and not to make movements himself until the character of his injury was established.

History. In civilian practice, the history of an injury of the eye is frequently use-

ful. It provides data concerning not only circumstances of the accident and the kind of foreign body, but usually also its force, direction, and possible infectiousness. In military injuries, the history is seldom of value, for even the type of weapon or shell used is often unknown. Therefore, potential infection must be assumed in all cases, regardless of the circumstances, although it may not be evident if the patient is seen promptly.

Examination. In cases of simple unilateral injury, the patient was placed in a partially darkened room, and pontocaine (0.5 percent) was instilled into both eyes before the examination. For more serious injuries, particularly the bilateral, local analgesia was secured with 4-percent cocaine solution, and adrenalin (1:1,000 solution) was instilled into the eyes in 2-drop amounts for four doses at 4-minute intervals. During this interim, sodium pentothal was administered intravenously, and no attempt at examination was made until the patient was fully relaxed. Black-silk sutures (4-0) were then placed in the upper and lower lids, in the areas in which procaine had been injected, and were used for purposes of retraction.

Thorough inspection with direct illumination was the first step of the examination. If hemorrhage and inflammation had not obscured the field, it provided useful information. In the majority of cases this was, unfortunately, not true. Hemorrhage had obscured the field, and the fundus reflex was absent. The examination was continued with the loupe and the ophthalmoscope; the slitlamp was used when feasible. The findings were correlated with the roentgenologic findings before any decision as to procedure was made.

Before discussing roentgenologic considerations, however, certain diagnostic considerations must be emphasized. It

was never assumed, because the lids were closed by hemorrhage or edema, or both, that the injuries were confined to the lids. These were gently retracted and intraocular foreign bodies were searched for, although it was sometimes necessary to delay the examination until compresses and other measures had reduced the edema and made manipulation possible without inflicting additional trauma. Intraocular examination was particularly necessary in cases of multiple wounds of the face, especially if edema and inflammatory reaction had already occurred when the patient was first seen. War ophthalmology provided no more difficult problems than delayed cases in which these changes had already obscured the intraocular field. The eyes in each such case were, therefore, thoroughly examined (the patient under sodium-pentothal anesthesia) and, if necessary, explored.

While the presence of a visible laceration of the cornea or sclera was regarded as presumptive evidence that a foreign body might have entered the eye, the absence of a visible wound was not considered adequate proof that it had not. A thin, small metallic fragment may leave no gross evidence of its entrance, particularly if some time has elapsed since the accident. When the staff of the 64th General Hospital worked close to the forward lines, or when patients were evacuated to it by air, the wound of entrance was usually visible. As the line went forward, or when patients were not seen until 24 hours or more had elapsed since their injuries, the wound of entrance was usually sealed and could not be demonstrated by any method of examination.

A prolapse of any portion of the uveal tract or of the vitreous, or a shallow deformity of the anterior chamber was regarded as *prima facie* evidence of a perforating wound with a possible intraocular foreign body.

A self-retaining retractor was never used in the search for a foreign body because it would exert pressure on the eyeball and contribute to the danger of loss of vitreous. Attempts to determine the presence of a perforating wound by pressure on the eyeball with the fingers or with a tonometer were also avoided. If a wound is present, such maneuvers inevitably cause the loss of vitreous.

The use of a magnet to test the presence of a foreign body was regarded as equally bad practice. If the body is nonmagnetic, the procedure is merely a waste of time. If it is magnetic, it may lie at too great a distance from the magnet, or be too small, or too deeply embedded in the tissues, to cause even a sense of pain until the instrument can be brought into closer contact with it. More important, if a magnetic foreign body is present and is susceptible to the pull of the magnet, a great harm may be done by even slight movement under noncontrolled conditions. Stallard's² suggestion that if fragments of the foreign bodies embedded elsewhere in the body can be removed, they should be examined roentgenologically to determine their constituents, seems to have definite limitations; for various explosives are made up of several different types of material. Some detonators, for example, as well as grenades and mines, consist of 90-percent nonmagnetic and 10-percent magnetic material. Furthermore, all the foreign bodies in a single case of injury are not necessarily of the same origin. Therefore, the practice of taking a foreign body from the face or other parts of the body to determine magnetism was not believed to be a reliable procedure.

ROENTGENOLOGIC EXAMINATION

Roentgenologic examination is the basic diagnostic method in cases of intraocular foreign bodies. Its success de-

pendes chiefly upon the roentgenologist, since the ophthalmologist does not usually have the requisite training to employ it. Collaboration between the two staffs is therefore essential. At the 64th General Hospital it was the practice for a member of the ophthalmologic staff to be present throughout the roentgenologic examination, and both staffs were thus familiar with all details of all cases.

Examination began with a postero-anterior view of the skull, followed by a lateral view, in all cases of suspected intraocular foreign bodies and of all multiple wounds of the face. The use of the Waters position excluded the confusing shadow of the petrous bone. A quick reading of the wet films was followed by accurate localization by two methods. First, a silver ring 22, 24, or 26 mm. in diameter, was slipped into the cul-de-sac after local analgesia with pontocaine had been achieved. A double exposure on the same plate was taken with the patient looking upward and then looking down, and a second double exposure was taken on another plate, with the patient first looking to the right and then to the left. Then, an accurate Sweet's localization was done and, if there seemed a chance of error, was repeated at the same sitting. The coördinates and master charts which were now available eliminated much of the tedious calculation formerly necessary in applying this method. The localization of the foreign body by the Sweet method was checked against that indicated in the postero-anterior view, and if the lateral and vertical films varied, localization was repeated until all the films agreed.

Special precautions were taken in all roentgenologic examinations. Certain cassettes were used only for eye work, and were kept scrupulously clean. All exposures were rapid. The importance of co-operation was stressed to the patient, and no distracting movements and noises were

permitted in the room. All films were checked while the patient was in the department and were repeated at once if there was any doubt as to their clarity. Only a few technicians, all of whom were carefully trained, were assigned to this work. They worked accurately because they knew that films must be made over if the findings of all methods of examination did not check with each other.

Errors are inherent in any method of localization, the most frequent arising from movements of the eye. In postero-anterior films this error was eliminated by having the patient look with the uninjured eye into an angled mirror at an object located laterally to him. If both eyes had been injured, the insertion of a silver ring helped to localize foreign bodies but did not completely exclude the error of movement or angulation of the eyeball or of the ring. The ring in a number of measured cases averaged 8 to 10 mm. behind the center of the cornea.

Several errors are possible in a double exposure on the same film, one of the most important being that a minute foreign body may not show up because it receives only half of the exposure ordinarily received. The foreign body may seem to be intraocular, while actually it is in the muscles, orbit, or fat, or in Tenon's capsule. Its presence in the eyelids was excluded by holding the lids open. Injection of air into Tenon's capsule followed by roentgenologic examination at several different angles, frequently clarified cases in which the foreign body had perforated the globe and lay just outside the sclera.

In several cases I found it possible to localize a foreign body by the use of four small lead beads sutured about the limbus in four different positions (case 5). Even if the patient should move, the foreign body was always in the same relationship to the beads. Sweet localization was done

Fig. 5 (Haik). Case 5. A, Localization of foreign body 1 mm. in diameter. Lead bead at limbus, ring method. Sweet method of localization. B, Lead beads at limbus, ring method, Waters's view. Foreign body removed on third attempt through posterior sclerotomy.

with the beads *in situ*, and the results of the two examinations were checked against each other. This method is much simpler than the use of a contact lens (case 6), which is undesirable because it introduces additional trauma and because its fit is only fair at best, eyeballs varying greatly in size and curvature, and estimates of the degree of error being only approximate. Stereoscopy associated with the lead beads and ring often furthered localization.

If the particle was so small that its shadow did not appear on the first film, repeated films of different densities often revealed its position. The use of dental films for the anterior segment was considered important for the demonstration of small foreign bodies of low density.

When it was feasible, a repetition of the examination by a second roentgenologist, or a rereading of the plates, particularly if they had been read while wet, proved useful. Fluoroscopy was disappointing. Its only real value was in the case of nonmagnetic foreign bodies, which as a rule were of such low density or of such small size that they were obscured by the bony structures.

It was the practice at the 64th General Hospital to explore the injured eye in

the region of the injury when the foreign body showed up in the double-exposure film as moving. The results of the examination were often inconclusive, and it was believed that the calculated risk of the operation was less than the risk of permitting a suspected intraocular foreign body to remain in the eye. It was also the practice to explore the eye in any case wherein there was reason to doubt a negative roentgenologic report

Fig. 6 (Haik). Case 6. Localization of foreign body with contact lens and lead beads. Angled mirror is in front of uninjured eye. Posterior sclerotomy removal.

and in any case wherein accurate localization was not successful, particularly if the foreign body were located 2 to 3 mm. from the sclera.

Mention should also be made of the foreign-body locator devised by Lieut. Col. Henry Carney on the principle of the apparatus used for detecting mines. While it was devised to locate foreign bodies elsewhere in the body, it was modified for use in the eye. It came into use shortly before the end of the fighting in Italy, and proved of value in confirming the X-ray findings.

OPERATION

The use of local analgesia was undesirable in military hospitals. The patients were frequently worn out and in a state of nervous tension when they were admitted; moreover, the inflammation so often present made complete anesthesia preferable. Sodium-pentothal anesthesia, supplemented by local analgesia, proved an ideal combination. It permitted maximum relaxation, and it was seldom necessary to section a muscle to expose the posterior sclera, which was often necessary when only local analgesia was used.

After the eyelashes had been clipped, the face was thoroughly washed with white soap and water, great care being taken to avoid pressure on the eyelids and eyeballs. The face was then wiped with 70-percent alcohol followed by tincture of merthiolate. Finally, argyrol in 10-percent solution was instilled into the eyes and was removed with copious irrigations of warm boric-acid solution.

Route of approach. Extraction of a foreign body through the wound of entrance was seldom feasible—a new incision usually had to be made. It was so placed as to permit removal of the object with the least possible trauma, and it was made

longer than the object, to prevent further tearing, since a controlled incision heals more readily than one with jagged edges. Although there continues to be argument as to whether removal should be by the anterior or the posterior route, there seems little reason for disagreement. It seemed only logical to place the incision so as to permit the most direct approach to the object. Fragments of missiles were likely to be irregular and rough; hence damage to the ciliary body, iris, lens, and other structures was almost inevitable if these fragments were dragged through the whole extent of the eye in order to remove them by way of a corneal incision. An additional reason for placing the incision as near the foreign body as possible was that the magnetism of many modern instruments of war was so low that the magnet, to be effective, had to be placed near the object.

Prejudiced adherence to either the anterior or the posterior route was regarded as equally unwise. As a general rule, however, when the foreign body lay more than a few millimeters beyond the posterior capsule of the lens, it was usually considered wiser to remove it through a posterior rather than an anterior incision.

Points of technique. The technique employed for posterior sclerotomy was simple. The affected area was completely cleared of conjunctiva, Tenon's capsule, and episcleral tissue. A black-silk suture (4-0) in the sclera was used as a retractor. A black-silk suture (7-0) on an atraumatic needle was introduced into the sclera just to one side of the foreign body for a depth of 0.1 mm., and a similar suture was introduced on the same level and to the same depth, just to the other side. An incision was made between these sutures, down to but not through the choroid, and the foreign body was re-

moved by magnet or forceps according to the indications; it was extremely important in dealing with minute foreign bodies to expose the choroid in view of their low magnetism. After the sutures were tied, the area about the incision was coagulated with the diathermy needle, to prevent detachment of the retina, a considered task in transcleral extraction. The episcleral tissue and Tenon's capsule were enclosed with interrupted silk sutures, care being taken that the incisions in the conjunctiva and sclera did not lie one above the other.

Corneal incisions and wounds were usually covered with conjunctival flaps and were sutured with atraumatic needles and with very fine black silk. The sutures did not penetrate more than half the thickness of the tissues.

If the foreign body lay in the anterior chamber or iris, eserine was instilled before the operation to contract the pupil, to keep the foreign body away from the lens, and to help prevent prolapse of the iris when the surgical incision was made. If the foreign body had perforated the lens and was lying in the vitreous posterior to it, making removal of the lens necessary, it was found that the best plan was to make the corneal opening just large enough to remove the foreign body, and to extract the lens at a second operation. This seemed advisable because vitreous is always present in the lens substance, and a large amount is likely to be lost if the lens and foreign body are removed together.

When a foreign body had been in the eye for any length of time, the vitreous was likely to be fluid and a large amount could easily be lost when the sclera was incised. Frequently, even a vitreous of normal consistency bulged into the wound. If this happened, the bulging portion was clipped off with scissors before the sutures, already placed, brought the cut edges of the sclera together.

Magnets. The small magnet, which was the only kind available in evacuation hospitals, was always used before the large magnet, if only because it was less awkward to manipulate. If it failed, the large magnet was applied. In the 64th General Hospital, successful removal of foreign bodies with a large magnet was possible in several cases in which the small magnet had previously failed. The difference between the two instruments, it should be emphasized, is not the increased magnetic attraction of the larger instrument, but the increased size of the magnetic field. Regardless of which is used, varying the distance between the patient and the tip of the magnet controls the degree of pull. In the ideal case, the tip of the magnet is applied either directly to the foreign body or at a distance of not more than 2 mm. Only after repeated attempts at more conservative methods have failed should probes, scissors, and other instruments be applied to the tip of the magnet, because when instruments are introduced into the vitreous, trauma is increased.

A magnet, whether large or small, was always used cautiously. It was never brought to the eye while alive. It was never used until the location and size of the foreign body had been determined as accurately as possible and the method of removal had been decided upon. Finally, it was introduced into the wound, as near the foreign body as possible, before the current was turned on. Repeated applications were sometimes necessary, and success was often achieved in most unlikely cases. Wright and Duncan³ have recently reported two such instances. In the first 6/6 vision was preserved in a German prisoner after 35 applications of the magnet and in the other 6/9 vision was preserved in an English soldier after 75 applications totaling 10 minutes and ranging in duration from 4 to 15 seconds, in the course of four operations.

Enucleation. Although enucleation is now a last resort in the management of foreign bodies, it was sometimes found to be the wisest procedure in the occasional case in which the object had damaged all the tissues of the eye in its passage or in which there had been a long delay before hospitalization, with the development of serious infection. When the injury was bilateral, it was particularly important to delay radical surgery. Sometimes the eye which on the first examination seemed in worse condition later proved to have better vision.

Experiences at the 64th General Hospital bore out the value of conservatism. In some cases as many as three attempts to remove the foreign body failed, but, unless the eye became painful and soft or light perception was permanently lost, enucleation was still delayed. In one such case, the result of an explosion of a 37-mm. gun, three attempts to remove a fragment (probably of aluminum) in the vitreous failed at this hospital. A fourth attempt in the United States also failed. Exploration was carried out through both the anterior and the posterior routes. The eye, however, remained quiet, and good vision was maintained. When the soldier was first seen, other, more superficial fragments were removed without difficulty from both eyes. Some of these were magnetic; others, nonmagnetic. Roentgenologic examination was negative in this case, the foreign body having been seen only by ophthalmoscopy.

The development of chemical endophthalmitis, even if severe, was not regarded as indication for immediate enucleation if the foreign body could be removed. In numerous cases treated at this hospital, the infection was controlled by foreign-protein therapy, and at least partial vision was preserved. The staff also took the position that because of the risk of sympathetic ophthalmia, immediate enuclea-

tion was not indicated in cases of injury involving the ciliary body. In a number of instances, in one of which the fragment was a 16-mm. piece of shrapnel, the foreign bodies were removed and useful vision was retained. All such cases were followed up for a minimum of three months, and no instance of sympathetic ophthalmia was observed during this period.

POSTOPERATIVE CARE

At the conclusion of the operation, 5-percent atropine sulfate was instilled into the eye, followed by sulfanilamide powder and 5-percent boric-acid ointment. The eyes were covered by a binocular bandage, and at the end of two weeks a pin-point shield was permitted on the uninjured eye. It proved impossible to keep the injured eye at rest if only a monocular bandage was used. The patient was warned against violent or abrupt movements, was kept in bed for seven or eight weeks, and was so supervised by the nursing staff that these instructions were carried out.

The postoperative management did not differ from the methods used in the usual ophthalmologic case except that atropine sulfate was used in 5-percent strength instead of in the usual 1-percent strength. This was necessary because of the difficulty of securing good dilation of the pupil in young men, the majority of whom have unusually strong sphincters.

It was standard practice in all eye injuries to begin the administration of penicillin in the evacuation or field hospital; 25,000 Oxford units was administered every three hours with as little interruption as possible until 2,500,000 units had been given. Before May, 1944, when penicillin first became available, sulfanilamide and its derivatives were used in all eye injuries.

Foreign-protein therapy was begun in

cases of perforating wounds as soon as the patient reached the General Hospital. Fresh milk was not obtainable; but canned milk, which, so far as I know, has not previously been used in foreign-protein therapy, gave excellent results. It was used in 5-c.c. amounts, mixed with 5 c.c. of distilled water, and was given five times every third day. No abscess resulted in more than 1,000 injections. The use of typhoid vaccine was usually undesirable when the patients were first seen, because many of them were in poor condition, if not in acute shock; however, if the eye continued irritable, it was employed later.

Infection was most likely to occur when the wound of entrance was through the cornea, and least likely to occur when it was through the sclera. The vitreous, fortunately, is a poor culture medium. In the cases in which chemotherapy had been instituted promptly, surprisingly few infections were observed at the 64th General Hospital, even when the patients were received late. Postoperative complications under the regime outlined were inconsequential.

SUMMARY AND CONCLUSIONS

The highly mechanized nature of modern warfare has caused a great increase in the number of injuries of the eye, but the application of modern therapeutic methods gives rise to the hope that the percentage of permanent and relative disability may be smaller than in previous wars.

Foreign bodies furnish one of the major ophthalmologic problems of military service. Their removal is never simple, but the risk of operation by a competent ophthalmologic surgeon, and under proper conditions, is less than the risk of their retention. Enucleation of the injured eye should be regarded as a last resort and never as the procedure of choice.

The exact localization of the foreign body by roentgenologic methods is the secret of successful removal. More than one attempt at removal may be necessary before success is achieved. Removal by magnet is desirable when it can be carried out, but an increasingly large number of missiles of modern warfare are nonmagnetic. The anterior or posterior approach should be used according to the indications.

The use of chemotherapy (penicillin and sulfanilamide and its derivatives) and of foreign-protein therapy (milk or typhoid vaccine) is successful in preventing and controlling infection in the majority of cases.

The removal of foreign bodies is attended with more difficulties in military than in civilian practices, but preservation of some degree of vision is possible in many unpromising cases. Even if enucleation must eventually be resorted to, the soldier should be given his chance for future vision, since conservation under proper safeguards, is not attended with undue risk.

THE EFFECT OF SUNLIGHT ON DARK ADAPTATION*

BRANT CLARK, LT. COMDR. H(S), USNR, M. L. JOHNSON, LT. (jg) H(W),
USNR, AND R. E. DREHER, LT. (jg) H(S), USNR
Pensacola, Florida

INTRODUCTION

Cases of night blindness attributed to exposure to excessive sunlight have been reported from time to time over a period of many years.¹ Although in most of these cases some dietary deficiencies may have been a causative factor, it seems likely, in view of recent reports^{2, 3, 4} on night visual disturbances occurring in military personnel, that exposure to bright sunlight may well have been an important contributing factor.

Recently reported are 50 cases of night blindness in the Turkish Army which were apparently due to bright sunlight.² Livingston,³ in a clinical study made in Iraq in 1932, found that constant exposure to sun glare resulted in definite clinical changes that are significantly detrimental to aviation, among other occupations. McCartney⁴ has also reported that exposure to tropical sunlight caused severe night blindness among military personnel in the South Pacific; in most of these cases the day vision remained unimpaired. He states further that cases of night blindness due to sun glare are more severe when other constitutional factors, such as alcoholism, dietary deficiencies, and reduced vitality of whatever cause, are also present.

These reports are substantiated by laboratory studies showing that the speed of dark adaptation is greatly influenced by the brightness of the light to which the eyes are exposed prior to dark adapta-

tion.^{5, 6, 7} For example, it has been shown that adaptation to high intensities of light prior to dark adaptation will not only delay the onset of rod adaptation, but will also delay the attainment of the normal, final dark-adapted threshold. In view of the foregoing and the persistence of reports of night blindness from combat areas in the South Pacific, further investigations on the effect of excessive sunlight upon retinal sensitivity have been made.

Hecht *et al.*⁸ undertook a study at Camp Lejeune in the fall of 1944, with the idea of determining how long the final dark-adapted threshold remains above normal after exposure to sunlight and whether such effects are cumulative in personnel exposed to sunlight day after day over a considerable period of time. They found that after a single exposure of two to three hours, the onset of rod adaptation was delayed for 10 minutes or more and the dark-adaptation process, itself, was delayed so that the normal dark-adapted threshold was not reached for several hours. After repeated daily exposures to sunlight, the night visual threshold remained elevated on an average of 0.11 log $\mu\mu$ lamberts above normal overnight. This degree of elevation amounts to a deterioration of about 50 percent in visual acuity, range of visibility, contrast discrimination, and frequency of seeing. Furthermore, this cumulative effect appeared to have some degree of permanence since it persisted even after 10 days of protection from sunlight.

Although there is ample evidence that prolonged exposure to sunlight has a deleterious effect upon night vision, the Bureau of Medicine and Surgery of the

Navy Department decided that additional data on certain practical aspects of the problem would be valuable. Two problems were considered to be of particular significance to Navy personnel assigned to duties involving the use of night vision: (1) the duration of the effects of sunlight on dark adaptation, and (2) the protection afforded by low-transmission sunglasses during exposure to sunlight.

The Naval Air Training Bases, Pensacola, Florida, offered a suitable place for these studies because there the bright sunlight and high reflectivity of the sand on the beaches closely approximate conditions of illumination found in the islands of the South Pacific. Furthermore, personnel and equipment were available for making the studies.

EXPERIMENTAL PROCEDURE

In the three experiments to be described, the testing of the subjects was done in the Night Vision Training Building, Naval Air Station, Pensacola. The building was ideal for the purpose, since it was lightproof, equipped with air conditioning, and had facilities for illumination by white or dim red light.

In each of the experiments, the subjects were tested in groups of 10 or less. In all cases each subject was dark adapted, prior to testing, by remaining in dim red light for 20 minutes and then in total darkness for 10 additional minutes. The dark-adapted thresholds of both the right and left eyes (or, in one experiment, of the sighting eye) were measured after 30 and 60 minutes of dark adaptation. In certain cases, thresholds were also determined after 90 minutes of dark adaptation.

The threshold measurements were made with a Hecht-Schlaer Adaptometer modified to present a 3-degree circular test patch. This was arranged to measure the monocular threshold of a retinal area

7 degrees above the macula. Each exposure of the test light was for one-fifth second. The method of limits was used to determine the threshold. The intensity of the test patch was decreased in 0.2 log μ lambert steps until the subject did not see two successive exposures. The intensity of the test light was then increased until the subject reported two successive exposures. Ten such series of trials were given, five descending alternated with five ascending series of trials. The average of these 10 measurements was taken as the threshold for each condition of adaptation.

The subjects used in these experiments were obtained from two sources. Two small groups consisted of enlisted men assigned to the Dispensary, NAS, Pensacola. The remaining men were members of seaplane beaching crews attached to Squadron 8-A NATB, Pensacola. In each case, before the experiment was started, the testing procedure and the purpose of the experiment were carefully explained to the subjects. Preliminary thresholds, obtained before the experimental conditions were instituted, served as practice periods to familiarize the men with the testing procedure and provided a basis for comparison with the thresholds obtained under experimental conditions. The men were exposed to sunlight for varying periods of time which will be indicated in the following discussion of the studies.

EXPERIMENTAL RESULTS

THE EFFECT OF EXCESSIVE SUNLIGHT ON THE RETINAL SENSITIVITY OF AN UNPROTECTED AND COMPLETELY PROTECTED EYE IN THE SAME INDIVIDUAL⁹

As a preliminary to an investigation of the protective value of sunglasses, an experiment was made to determine whether the effect of sunlight on retinal

sensitivity of an unprotected and a completely-protected eye could be studied simultaneously in the same individual. This was done by measuring the monocular variation in night visual thresholds of four subjects who had one eye completely protected by a black eye shield during exposure to bright sunlight. After preliminary threshold measurements had

periment, the eye patch was reversed and worn on the left eye.

The combined data are shown graphically in figures 1 and 2. The afternoon data (fig. 1) show the immediate effects of excessive sunlight on the night visual thresholds, whereas the morning data (fig. 2) show any residual effect of the previous day's exposure. The difference

Fig. 1 (Clark, Johnson, and Dreher). Afternoon dark-adapted thresholds.

been made, each man was issued a black eye shield and instructed to wear it over the right eye at all times while out-of-doors except after sundown. The men were sent to Mustin Beach on Penascola Bay every day except Sunday during the experiment. Throughout the experiment every day was sunny and bright. The men averaged 4 hours and 25 minutes a day on the beach, during which time they were permitted to do whatever they wished to amuse themselves, so long as they did not close the exposed eye or protect it from the sun or sand in any way. After the morning tests on the 15th day of the ex-

periment, the eye patch was reversed and worn on the left eye.

in threshold, which was negligible at the beginning of the experiment, may be used as a measure of the effect of sunlight upon the exposed eye.

As would be expected, the effects of exposure to sunlight were most marked in the afternoon, immediately following exposure. It can be seen in figure 1 that the average afternoon thresholds of the exposed eye were always higher than those of the protected eye. After 30 minutes of dark adaptation, the differences in favor of the protected eye ranged from 0.11 to 0.50 log $\mu\lambda$ lamberts, with an average difference of 0.34 log $\mu\lambda$ lam-

berts (table 1). After 60 minutes of dark adaptation, the same effects were present to a lesser degree, the range for the group being 0.07 to 0.30 log $\mu\mu$ lamberts, with an

the threshold of the formerly protected eye rose 0.30 log $\mu\mu$ lamberts above its previous, and presumably normal, level for the duration of the experiment. After

* Final four days only.

† Final three days only.

average difference of 0.21 log $\mu\mu$ lamberts (table 1).

When the eye shields were reversed on the morning of the fifteenth experimental day, the thresholds taken that afternoon showed marked reversals (fig. 1). After 30 minutes of dark adaptation,

60 minutes of dark adaptation, an elevation of 0.20 log $\mu\mu$ lamberts persisted through the final eight days. On the afternoon of the first day it was protected from the sun, the previously exposed eye, now protected with a black shield, showed threshold drops of 0.35 and 0.25 log $\mu\mu$

lamberts after 30 and 60 minutes of dark adaptation, respectively. Furthermore, the thresholds of the previously exposed eye remained at this lower level through the remaining seven days of the experiment. On the last three afternoons of the experiment, thresholds measured after 90 minutes of dark adaptation showed that the exposed eye had reached in 90 minutes the level normally attained by the protected eye after only 30 minutes of dark adaptation (table 1).

The residuum of the effect of the previous day's exposure is shown in the 30- and 60-minute threshold measurements taken in the morning before the daily exposure to sunlight (fig. 2). The effect here was the same as that found in the afternoon data, except that the decrement of rod function in the exposed eye was less. After 30 minutes of adaptation, the average difference between the two eyes was $0.13 \log \mu\mu$ lamberts with a range of 0.10 to $0.44 \log \mu\mu$ lamberts. Following 60 minutes of adaptation, an average difference of $0.12 \log \mu\mu$ lamberts between the two eyes was present (table 1). After reversal of the eye shields on the fifteenth day, shifts in sensitivity similar to those present in the afternoon appeared in the morning data. The threshold of the formerly exposed eye dropped to the level of the previously protected eye, and that of the previously protected eye (now exposed) rose to the level of the previously exposed eye.

These data reveal effects of exposure to sunlight that are of the same order of magnitude as those found by Hecht *et al.* at Camp Lejeune.⁸ Although the amount of the elevation in threshold is not spectacular, Hecht has pointed out that it is enough to reduce efficiency by approximately 50 percent at threshold levels of intensity. These results differ from those of the Camp Lejeune study, however, in that the effects of the exposure were

found to be only temporary. In the present study, the elevation of threshold of the exposed eye disappeared when the eye was completely protected from light for a period of seven to eight hours during a day, while the other eye was exposed to brilliant sunlight.

A STUDY OF THE EFFECTIVENESS OF SUNGLASSES IN THE PROTECTION OF NIGHT VISION

Two studies were made to determine the effectiveness of Navy-issue sunglasses having 12-percent transmission, polarizing, neutral filters (Sun, N-1, Contract No. NXsX-66884). One was a field study of 20 members of four seaplane beaching crews.¹⁰ The other was a laboratory study made on a group of three men attached to the Dispensary, NAS, Pensacola.¹¹

Field study. The men from the seaplane squadron (Squadron 8-A) were selected because they had been working on the seaplane ramps for a number of months and had been exposed to sunlight from six to eight hours per day during this period. With such subjects it was possible to determine the protection to night vision afforded by wearing low-transmission sunglasses under operating conditions at a Naval Air Station.

After preliminary threshold measurements, the 20 men were divided into two groups. One group was issued glasses and the other was not. The men with the glasses were instructed to wear them at all times while they were out-of-doors. The remaining men carried on their work as usual and thus acted as a control group. The experimental conditions for the two groups were reversed on the fifteenth day of the experiment.

There was a negligible difference between the two groups during the preliminary tests. However, when one group wore the glasses there was a consistent

threshold difference between the two groups, favoring those who were protected. As table 2 shows, the differences in the afternoon thresholds were 0.21 log $\mu\mu$ lamberts after 30 minutes of dark

adaptation and 0.22 log $\mu\mu$ lamberts after 60 minutes of dark adaptation. These thresholds were taken after approximately three hours' exposure to sunlight. As in the previous experiment, the morning data show similar but smaller differences (fig. 3). The average differences in these morning thresholds were 0.17 log $\mu\mu$ lamberts after 30 minutes and 0.15 log $\mu\mu$ lamberts after 60 minutes of dark adaptation (table 2). Due to inclement weather at the time the groups were reversed, the data at this point are somewhat obscure, but there was a trend toward a reversal of the thresholds of the groups. The final point on the curve (fig. 3) is the average from the 18th and 20th days.

The data indicate that the low-transmission sunglasses used in this experiment afford excellent protection to the retinal sensitivity of persons working in

sunlight for prolonged periods. The protection is sufficient to result in higher visual efficiency of practical importance to those engaged in visual tasks at night.

Laboratory study. In a more carefully controlled experiment, a group of three men was studied with the same technique

as that employed when the eye shield was used. Here, however, a 12-percent polarizing neutral filter was worn over one eye instead of an eye patch. The exposure to sunlight varied between three and four hours per day.

The results followed the same pattern

Fig. 4 (Clark, Johnson, and Dreher). Afternoon dark-adapted thresholds. $N = 3$.

TABLE 3

AVERAGE THRESHOLDS OF EXPOSED EYES
AND EYES PROTECTED WITH SUNGLASSES

	Mean Morning Thresholds in Log $\mu\mu$ Lamberts		Mean Afternoon Thresholds in Log $\mu\mu$ Lamberts	
	Dark-Adaptation Times		Dark-Adaptation Times	
	30 min.	60 min.	30 min.	60 min.

Average difference	0.13	0.13	0.24	0.19

found with the eye patch. When the subjects were exposed to sunlight for extended periods, there was an immediate and marked elevation in the threshold of the unprotected eye as compared with the protected eye (fig. 4). After 30 minutes of dark adaptation this amounted to 0.24 log $\mu\mu$ lamberts and after 60 minutes to 0.19 log $\mu\mu$ lamberts (table 3). This higher threshold persisted overnight and amounted to 0.13 log $\mu\mu$ lamberts after both 30 and 60 minutes of dark adaptation in the morning tests (fig. 5, table 3). When the filter was changed to the left eye, there was an immediate reversal of sensitivity in the two eyes. Here again, as

in the eye-shield study, the immediacy of the reversal in threshold sensitivity following reversal of the experimental conditions indicates that the threshold elevation in the exposed eye was only temporary.

These results show clearly that the sunglasses used in this experiment are effective

two weeks show a marked elevation of the night visual threshold immediately following exposure. The degree of elevation persisting overnight is sufficient to cause approximately a 50-percent loss in night visual efficiency. Furthermore, it appears that persons exposed to sunlight for extended periods daily, without pro-

Fig. 5 (Clark, Johnson, and Dreher). Morning dark-adapted threshold. $N = 3$.

tive in providing protection of the retinal sensitivity of persons exposed to sunlight for prolonged periods. They also indicate that the 30-minute period of dark adaptation generally required for obtaining a practical maximum of night visual efficiency is inadequate for persons who have been directly exposed to sunlight for extended periods through the day.

SUMMARY

Individuals exposed to sunlight for three to four hours a day over a period of

tection to their eyes, require in excess of one hour of adaptation to achieve a practical maximum of night visual efficiency. Exposure to brilliant sunlight has been reported as the cause of night blindness that is more or less permanent. However, the present studies on normal individuals indicate that the effects of daily exposure for three to four hours are only temporary, since the threshold returns to normal after one day's protection from the sun.

Persons wearing 12-percent transmis-

sion polarizing sunglasses during prolonged exposure to sunlight had significantly lower night-visual thresholds than those who did not. In view of these results, personnel engaging in night duties requiring a high degree of night visual

efficiency at starlight intensities should be provided with low-transmission sunglasses to be worn during any daytime activities which expose them to excessive sunlight.

OBSERVATIONS ON THE VOSSIUS RING*

TRYGVE GUNDERSEN, MAJOR (MC), A.U.S.

Washington, D.C.

Vossius ring is the eponymic term for a well-known ring occasionally seen on the anterior capsule of the crystalline lens of only young individuals, following trauma. Various writers have used other terms for it, usually to indicate its cause or appearance; such as, contusion ring, traumatic annular opacity, ring deposit.

Vossius first described this now-famous ring in 1903 and made a more comprehensive report on the subject before the International Congress of Ophthalmology, at Lisbon, in 1906. He distinguished two forms, a colored one which he said came from the pars ciliaris iridis, and a colorless one which he attributed to degenerative changes in the lens-capsule epithelium and possibly in the anterior cortical layers of the lens. The latter, he said, was more rare than the former.[†] Vossius ascribed the ring to an opacity in the capsule and possibly in the underlying anterior cortex of the lens, presumably caused by the impact of the iris against these tissues. Even in his last paper on this subject, in 1908, he held the same opinion.

The original theory of Vossius implied that the cornea was actually indented so that its posterior surface came in direct contact with, and forced the iris border against, the lens. The possibility that this could happen was promptly denied by many observers. Hoeg (1909) contested it on four grounds: the ring was almost

always complete, it was regular in form, the inner border was no denser than the outer, and, finally, the object causing the contusion would need to be of about the same size in all cases. He therefore suggested that a momentary rise in ocular pressure was sufficient to effect the same result. Steiner (1910) and shortly thereafter Purtscher (1913) described cases in which the injury had been *vis a tergo*, that is, by penetrating wounds of the posterior orbit. The corneas had suffered no direct trauma whatever. Few writers held to the old Vossius explanation after Hoeg's objections. Notable among them were Klauber (1918), Behman (1920), and Urbanek (1923).

Not until 1918 did Hesse and, shortly thereafter, Vogt show that the ring was not an opacity in the lens or lens capsule, but a thin ring of deposit on the former.

Severe trauma and intraocular hemorrhage are the two most constant factors. Vogt states that a Vossius ring has never followed nontraumatic hyphemia, and he believes the instance which Hesse reported, wherein a ring followed a vitreous hemorrhage twice punctured surgically, to be an "iritis ring."[‡] Hesse, who believes that the hemorrhage is more important than the trauma, brings forth the following evidence to support his views. He cites two cases in which the ring was seen following anterior-chamber hemorrhage, in which the trauma was insignificant; also Zentmayer's case, confirmed by

* From the Surgical Consultants' Division, Ophthalmology Branch, Office of the Surgeon General. Read before the eighty-first annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, November, 1945.

[†] Although I have never seen the colorless transparent form, E. Cramer gives an excellent example of one.

[‡] In his "Atlas of slit-lamp microscopy" he illustrates the difference, pointing out that the iritis ring is broader, its individual dots larger and more irregular in size, and also that free pigment dots appear on the capsule about the periphery of the ring.

Holloway, wherein a ring appeared after an anterior-chamber hemorrhage which followed an advancement operation. The iridic vessels were inadvertently injured by the needle penetrating, or possibly perforating, the sclera.

The period of time between the contusion and the appearance of the ring would seem to answer the question as to whether it was composed of iridic elements left behind on the lens when the two tissues were forcibly compressed against each other, or whether the ring was blood corpuscles or other blood elements secondarily deposited from intraocular blood, especially blood from the anterior chamber. The fact that no one has ever reported seeing a ring immediately after injury seems to prove there was none to observe. The shortest interval between the injury and discovery of a ring was two hours (Urbanek's case). In the great majority of cases the ring was not discovered until approximately four days after injury. It is claimed that delay in discovery is due to hindrances to examination—often the injury is immediately followed by bleeding in the anterior chamber or clouding of the cornea, either of which may obscure the picture. Or, more often, pain, irritation, and swelling of the lids make an accurate examination impossible. These reasons could account for the interval before discovery in most cases, but not all. If trauma were the direct cause, there would be at least a few cases in which the ring was observed immediately.

No instance of a ring has been observed in the absence of visible intraocular blood, or where the possibility of pre-existing intraocular blood has been excluded. Hesse is doubtless the first and strongest exponent of the hematogenous theory of origin. He points out that in certain instances a complete disc is deposited over the anterior lens capsule, the

center of which first becomes absorbed, hence leaving a ring. Caspar previously described such a case, wherein only after the coagulum overlying the capsule had become absorbed, did the complete ring appear. Peters, too, contends that the deposit is blood pigment rather than iridic pigment. He furthermore draws an analogy between it and hematogenous pigmentation of the cornea, and finds a similarity between the fine brown granules in the Vossius ring and the "fibrin crystals" which Leber described in the hematogenously pigmented cornea. The relatively short period of time occurring between the contusion and the appearance of the ring is the strongest argument against the similarity of these two deposits.

Exactly how a sudden rise in ocular pressure could cause pigmented particles from the iris to become fastened to the smooth lens capsule is not clear. Presumably, the rise in hydrostatic pressure in some manner would squeeze the iris tissue with sufficient force to cause interstitial fluids containing pigment granules and protein to leave the iris and become fastened to the capsule by fibrin. This is the so-called "abklatsch theory" which has the greatest number of supporters, notably Vogt, A. Jess, and others. A supplement to this idea was proposed by O'Asaro Biondo, who suggested that the lack of hydrostatic equality between lens and iris was an important factor. The inertia of lens being greater than that of iris caused sudden contact between them when the pressure wave traveled through the ocular media.

Handmann contributed a notable paper on Vossius rings in 1930, and carefully reviewed the literature to that date. He strongly supported the hematogenous theory of origin, but denied that contusion was invariably necessary. He likewise pointed out the similarity in size of

the rings which he had seen and those previously reported in the literature. On the basis of these observations he denied that the iris had anything to do with the pathogenesis and proposed a new theory of origin. He cited the detailed work of Busacca and Melli on the anatomy of the lens capsule; especially that the zonular lamellae, after fanning out over the equatorial surface, completely disappeared in just the area occupied and enclosed by the Vossius ring. Presumably, according to Handmann, the osmotic interchange of metabolites occurs in this area, where the capsule is devoid of one membranous layer, and it was not surprising to him that blood derivatives became fixed to the capsule, and indeed in the capsular pores at this point. The fact that the senile lens is immune to this process was explained by its decreased porosity. Handmann further speculated on the effect of the temporary stoppage or slowing down of the aqueous convection currents which often follow trauma. His interpretation was that the stagnation favored the deposition of blood or blood pigments on the capsule. Questions which were left without answer were, why Vossius ring so rarely, if ever, follows non-traumatic hyphemia; why it is always seen in its regressive and never in its formative stage; and what effect contusion has in initiating the process?

A single histologic examination might prove whether the particles deposited on the lens capsule were fuchsin bodies from the pupillary pigment epithelium or blood elements, but not to my knowledge has such an examination ever been made.

My interest in this subject was first stimulated when I observed that four soldiers, simultaneously in the hospital for contusions and penetrating wounds of the orbit, had Vossius rings of the same size. This seemed particularly interesting since their injuries had occurred

during the day, in two instances, and in the other two instances, during the night. The imprint of the pupillary margin on the anterior lens capsule should occur instantaneously at the moment of contusion and hence record either a contracted or dilated pupil. As more Vossius rings were seen in new patients, this uniformity in size was confirmed in every one. It first seemed possible that the pupil might have contracted following the light-flash stimulation, before contusion occurred, but since this pupillary light reflex is slow—0.2 to 0.5 seconds—and the blast wave very fast—12,000 ft. per second—it was obvious that this could not have happened. Even shell fragments which scatter at 6,000 ft. per second, striking the eye, would precede the pupillary reflex. Another pupillary reflex, that due to direct pressure on the globe, may also be considered here. Von Berlin and Gaille have described it, but to my knowledge its speed has not been measured.

PERSONAL OBSERVATIONS

During 10 months, 19 Vossius rings were seen in 15 patients; that is, four of these had bilateral rings. They all occurred in young American soldiers 19 to 30 years of age. All had been wounded in battle, six by mines, eight by shell or grenade fragments, and one by a rifle bullet. Contusion of the globe without perforation accounted for 13. Eight of these had multiple penetrating wounds of the cornea with retained foreign bodies in addition to contusion. There were three patients with intraocular foreign bodies; two had been removed before the Vossius ring was seen, and the third had multiple foreign bodies visible on the iris.

Intraocular hemorrhage was present in every eye. Thirteen showed blood in the vitreous. Except for the last two patients listed, who had massive vitreous hemorrhages and who had had intraocular

foreign bodies extracted by the posterior route, the vitreous hemorrhages were localized and circumscribed near the retina and usually in the far periphery. Hyphemia was seen in only two eyes, but

A transparent millimeter ruler was held as closely to the cornea as possible without actually touching it. The diameter was then measured as seen through a convex lens of an ophthalmoscope (+8.00D. sph.)

was doubtless present in many others before the patients came to the hospital. In only four eyes was it impossible to find extensive retinal or vitreous hemorrhage. These eyes did have cellular elements visible in the aqueous on slitlamp examination, doubtless blood cells.

The size of 19 contusion rings varied between 2.25 and 2.75 mm. as measured by the following relatively crude method:

without making any correction for its magnification by the cornea. The width of the band forming the ring could not be measured by this method. On correlating this uniform diameter of the ring with the size of the pupil at the time of injury, the following analysis is interesting: Eight injuries occurred during daylight hours, five during darkness, and one at twilight. It is therefore clear that the size of the

Vossius ring bears no relation to the size of the pupil before injury occurred.

Certain other physical characteristics of the ring are worthy of mention, and one in particular constitutes strong evidence against the theory that it is an impression of the pupillary margin on the anterior lens capsule. The ring is composed of fine brown dots arranged in an evenly distributed pattern. Its outer border is perfectly smooth, but its inner border, which is the nearer to the smooth free iris border, is distinctly irregular. Groups or clusters of particles extend toward the center of the pupil in a manner which gives this margin a scalloped or even saw-toothed appearance with the slitlamp. If the Vossius ring were an imprint of the pupillary margin, one would expect that the inner border of the imprint, corresponding to the free iris margin, would be smooth, whereas the outer might or might not be. That the reverse is true is additional strong evidence that the iris margin is not imprinted on the lens capsule. The smooth outer border is more likely to be so delimited for some other reason; such as, an abrupt anatomic change in the lens capsule at the equatorial region.

OBSERVATIONS ON CONDITIONS ALLIED TO VOSSIUS RING

It is desired at this time to draw attention to a condition I have observed in two patients which I believe is pathogenically related to the Vossius-ring phenomenon.

The first patient was a soldier, aged 20 years, with sympathetic uveitis. He was first seen by me 11 weeks after a shell fragment had perforated his left eye and 5 weeks after the onset of uveitis in his right eye. His right eye had been atropinized since he first noticed blurring of vision, and the pupil had been well dilated at all times. Vision was 20/50. The

injured eye had been removed two weeks after sympathetic ophthalmia began, and on pathologic examination showed inflammation consistent with sympathetic uveitis. The sympathizing eye was slightly congested. There were keratitic precipitates covering almost the entire posterior surface of the cornea, increasing in number and size over the lower half in characteristic fashion. Similar precipitates also covered the anterior lens capsule. These were generally more uniform in size and distribution than those on the cornea. The important observation was that within a perfect circle, measuring 2.75 mm. in diameter on the center of the anterior lens capsule, there was a distinct area of clearing of the precipitates. Although not absent altogether, they were smaller in size and more sparsely distributed. The clear disc was best seen when viewed through the ophthalmoscope.

The patient was again seen nine weeks later. The disc of clearing was still perfectly obvious, although less well demarcated.

When observed through the slitlamp, this particular portion of the lens capsule appeared to be covered with a delicate, lacelike film with knots comprising the precipitates. The latter were not invariably joined together but usually had several spicules extending toward their neighbors. No spicules extended into the anterior chamber. The precipitates themselves were gray and faintly pigmented. There were many fine cellular elements circulating in the aqueous, but no Koeppe nodules could be seen on the iris margin.

Since describing this finding to Dr. David G. Cogan, four months ago, he has told me that he too has observed this clear disc on the anterior lens capsule of a patient with chronic uveitis. Although its actual diameter was not meas-

ured, he, in retrospect, estimated it to be about 2 to 3 mm.

DISCUSSION

As can be seen in the foregoing narrative about Vossius rings, much has been written about them. These writings are found almost entirely in the foreign literature. The subject as a whole does not seem to have stimulated much interest either in America or in England. In fact, I have yet to find an American ophthalmologist who has entertained any other theory of origin than that originally proposed by Vossius.

Although there is still much to be learned about the conditions, it seems wise at this time to assemble the knowledge gained from the important contributions cited, add to them observations which I myself have made, and finally sort out the factual from the fanciful ones.

The following facts seem clearly established:

Vossius ring is almost without exception the result of trauma. Zentmayer's patient, who certainly had a minimal amount of trauma, did have a tiny perforating wound and in addition the surgical trauma attending any advancement operation. Hesse, who has been the strongest exponent of the hematogenous theory of origin, stresses the importance of intraocular blood, at the same time minimizing the importance of trauma. In two of his cases he mentions that they had no "significant" trauma but does not say they had none whatever. I believe, therefore, that the existence of a nontraumatic Vossius ring has never been proved.

Intraocular hemorrhage is also a wholly constant finding. It was present in each of my 19 cases and in no reported case has its presence been excluded. Blood

may be found either in the retina, vitreous, or aqueous. Often it is found in two or all three of these structures. That intraocular hemorrhage is such a constant factor is strong presumptive evidence that it plays an etiologic role.

Senile and presenile eyes seem to be immune to Vossius-ring formation. So far as I know, a ring has never been recorded in the eye of a patient after the beginning of the fifth decade.

Vossius rings have been seen only in the regressive and never in the formative stage. This is a significant fact, and until the formative stage has been observed it constitutes the weakest link in the hematogenous theory of origin and a strong argument for the "abklatsch theory." In my opinion it is likely that some day a ring will be seen to form, since other evidence points so strongly to the idea that they are composed of blood pigments. The fact that they have not to this day been observed in their developmental stage may be explained by their rarity, the difficulty in adequately examining a freshly injured eye, the fact that hyphemia so often obscures the lens capsule and, probably more important, that they escape our notice until completely formed. We see only that for which we are searching.

Vossius rings have never been observed immediately after injury. As previously mentioned, two hours is the earliest interval between injury and observation. This time interval does not exclude the possibility that iridic pigment may have been deposited at the time of contusion, but it is evidence against it. If the ring be of blood pigments; or blood derivatives, two hours seems an incredibly short period of time for them to be deposited. However, the vast majority are seen days after injury, and since errors in observation are always

possible, the common prolonged latent period is probably more significant.

The constant size of Vossius rings has now been established. In the 19 cases reported, the variations in diameter did not exceed one-half millimeter, and in every reported case, where measurements have been recorded, the size is practically identical with those I have reported. As previously pointed out, this in itself practically excludes the possibility that the iris margin has left its imprint on the lens capsule.

Finally, a characteristic which I believe is constant is the smoothness of the outer border and irregularity of the inner border of the Vossius ring. This is further strong evidence against the "abklatsch theory" of origin.

The following questions remain without answer or are purely in the realm of speculation: If the ring is not caused by an impression of the iris margin, what is its cause? What are the fine brown granular deposits which one sees with the slitlamp? Why is the ring of constant size? Why is trauma a necessary factor, or why does the ring never follow nontraumatic hyphemia? Finally the question arises—What is the relationship between the Vossius ring and the disc of clearing which I have described in uveitis?

Handmann has thrown considerable light on these questions. Since the lens capsule loses its zonular lamella somewhere in this region, one might assume that it occurred exactly at the outer margin of the Vossius ring. This would account for its regular size, and since the theory accepts the hematogenous origin, it would follow that the brown deposits are blood pigments. The greater interchange of fluids between aqueous and lens through this thinner area of the capsule

reasonably explains the deposition of a disc of blood pigment within this circle. It seems to me it also explains the relative clearing of these and other deposits in the central area. But the fact that a ring is the rule and a disc is the exception, cannot be satisfactorily explained with our present knowledge. It may be that the circulation in the anterior chamber is temporarily abolished as suggested by Handmann, but this must also occur in some cases of spontaneous hemorrhage. In my opinion trauma must have some other effect. An explanation of this important point awaits further elucidation.

CONCLUSIONS

1. Nineteen cases of Vossius-ring formation are reported.

2. All occurred as a result of battle injury in American soldiers between the ages of 19 and 30 years.

3. Intraocular hemorrhage was found in every eye.

4. The size of the ring was practically constant in all cases—2.25 to 2.75 mm. were the limits of variation in their diameters.

5. It is concluded that the ring does not consist of iris pigment left behind on the lens capsule as a result of the injury.

6. The most tenable explanation for the formation of the Vossius ring is that blood pigments from the aqueous are deposited in characteristic fashion during the interchange of fluids through the anterior lens capsule.

7. A disc of clearing is described on the anterior lens capsule in a case of uveitis. This is thought to indicate that interchange of fluids through the anterior lens capsule takes place chiefly here.

SACCULAR PROLAPSE OF THE VITREOUS BODY*

REPORT OF CASE

RALPH A. POIRIER, M.D.

Rochester, Minnesota

Hernias of the vitreous body into the anterior chamber of the eye may be classified into three groups according to Paula-Santos:¹ (1) hernias following intracapsular extraction of cataracts; (2) hernias following the rupture of the vitreous body after discission of the lens or an aftercataract; and (3) hernias following displacement of the lens into the anterior chamber. In the first group the vitreous body remains intact and the hernia usually occurs as a symmetrical protrusion into the anterior chamber. After several days the hernia may recede to normal position. In the third group hernias occur after rupture or partial disinsertion of the zonule. This group includes congenital, surgical, and traumatic displacements of the lens.

Hernias resulting from traumatic displacement of the lens may have two distinct forms: (1) no definite anterior limiting membrane; (2) a distinct anterior limiting membrane covering the vitreous which is in the form of a sac or a

drop. This saccular form is extremely rare. Blood may be placed in the dependent portion of the sac and almost without exception pigment is deposited on the anterior limiting membrane in a kaleidoscopic fashion. The anterior limiting membrane may appear as a single layer or it may appear to be laminated. Duke-Elder² stated that this distinct anterior membrane is probably a mechanical effect of the tension and stress created by the prolapse on the micellar structure of the vitreous causing a rearrangement, a re-orientation, and a condensation of its fibrillar contents. Cowan and Fry³ offered anatomic and histologic evidence that a hyaloid membrane existed as a nonnuclear, structureless, uniformly staining membrane. This membrane was attached to the pars plana of the ciliary body and separated the aqueous from the vitreous chamber. Previously Cowan⁴ stated that the membrane might be a proliferation of the vitreous surface but not a condensation.

REPORT OF CASE

The patient, a white man, came to the

* Fellow in Ophthalmology, The Mayo Foundation.

Mayo Clinic on July 2, 1945. The right eye had been injured by a football in 1918, at which time he had partial loss of vision. In 1929 he noticed that the right eye was divergent and that its vision was limited to perception of moving objects. On June 9, 1945, the right eye became extremely painful and red. He consulted an ophthalmologist and was informed that a cataractous lens was dislocated into the anterior chamber and was causing irritation. He was given atropine to use twice daily. The eye remained red but the pain gradually subsided. However, on June 27th, the eye again became extremely painful. His physician, at this time, advised an operation to reduce the intraocular pressure. He consulted another ophthalmologist shortly thereafter and was told the pressure was normal.

Examination at the Clinic revealed visual acuity of 1/60 in the right eye and 6/6 in the left eye. The right eye was 30 degrees divergent. Pupillary reflexes were absent in the right eye but were prompt in the left eye. Further examination of the left eye revealed no abnormalities, so the following comments pertain only to the right eye. The eye was free from inflammation except slight circumcorneal injection. The iris was tremulous and remnants of the lens capsule were discernible in the anterior chamber. The fundus was seen poorly but appeared normal. Biomicroscopy revealed that the cornea was clear, the anterior chamber deep, and the pupil 4 mm. in diameter. Saccular herniation of the vitreous had occurred through the pupil. The vitreous was confined by an intact anterior limiting membrane which could be outlined clearly. There were numerous deposits of pigment on the surface of the limiting membrane. Remnants of the lens capsule were firmly attached to its anterior surface. The vitreous gel posterior to the anterior limiting

membrane was optically clear. There was practically no aqueous in the anterior chamber. Intraocular pressure was 25 mm. Hg (Schiotz) in the right eye, and 22 mm. in the left eye. Tension on July 9, 1945, was 45 mm. Hg in the right eye. The acute glaucoma was probably due to the nearly complete filling of the anterior chamber by the intact herniated vitreous which partially obstructed the filtration angle.

The patient was given miotics and operation was advised to reduce the tension and to clear the pupil of opacities for vision. On July 12, 1945, a small incision was made at the upper limbus with a keratome. The vitreous immediately presented at the incision and was removed. Capsular remnants of the lens attached to the anterior limiting membrane of the vitreous were removed with forceps.

The patient made an uneventful recovery. Refraction on July 25, 1945, revealed that with +10.50D. sph. \approx +2.75D. cyl. ax. 125°, the visual acuity was 6/7. With the addition of a +3.0 sphere, his visual acuity was 14/21, according to the American Medical Association reading chart.

COMMENT

Traumatic herniation of the vitreous body into the anterior chamber is rare.^{1, 5, 6, 7} It is easily recognized by the biomicroscopic examination.^{8, 9} Whether or not blood was present in the dependent portion of the sac in this case would only be conjectural. However, the many scattered deposits of pigment on the anterior limiting membrane may have been the result of hemorrhage.

The anterior limiting membrane in this case was probably a new formation. Paula-Santos¹ called attention to the fact that if the hyaloid membrane is not broken, it must be quite elastic to permit

the vitreous to protrude through the pupil. Then by virtue of its own elasticity it should assume its original position and thereby reduce the herniation. It is more reasonable to assume the formation of a new membrane resulting from a physiochemical response between the vitreous and the aqueous humor rather than a

stretching of the hyaloid. It cannot be satisfactorily demonstrated anatomically; moreover, Duke-Elder¹⁰ has shown that the entire vitreous body will pass through a filter paper leaving behind no residue except a homogeneous protein material which is not derived from the surface of the vitreous.

CYCLODIALYSIS IN THE TREATMENT OF GLAUCOMA*

SAMUEL D. MCPHERSON, JR., M.D.

Baltimore, Maryland

Cyclodialysis was described by Heine in 1905 as a procedure for the surgical treatment of chronic primary glaucoma.¹ Since then it has been used in the treatment of all recognized types of the disease. It is the purpose of this paper to report the results in 140 cases when cyclodialysis was performed. These cases may be divided into three categories: (1) chronic primary glaucoma, (2) glaucoma following cataract extraction, and (3) glaucoma secondary to active uveitis.

MATERIAL

This report is based on the case histories of patients with these three types of

TABLE 1

RESULTS OF CYCLODIALYSIS IN CHRONIC PRIMARY GLAUCOMA, GLAUCOMA FOLLOWING CATARACT EXTRACTION, AND GLAUCOMA SECONDARY TO UVEITIS

Type of Glaucoma	Cases Followed One Year	Cases with Tension Less Than 30 mm. Hg (Schiotz)	Percentage
Chronic primary	45	19	42
Following cataract extraction	39	14	35.9
Secondary to uveitis	31	2	6.5

glaucoma in whom cyclodialysis was performed in the Wilmer Institute between January 1, 1927, and January 1, 1944. In determining the final results in the three types of glaucoma, the classification "success" was used only in those histories with follow-up periods of one year or more; the definition of "success" being

that the tension was controlled within normal limits for a minimum period of one year. On the other hand, for the classification "failures," all case histories were used in which there was any record of consistently or repeatedly elevated tension after the operation, irrespective of the period of observation. In all cases the tension was taken with a Schiotz tonometer, and any tension over 29 mm. Hg was considered elevated. Operations in all cases were performed by members of the resident or full-time staff of the Wilmer Institute.

RESULTS

The results in these three types of glaucoma are given in table 1.

Chronic primary glaucoma. Cyclodialysis was performed in 56 eyes with chronic primary glaucoma. In 12 of these cases, cyclodialysis was performed as the initial procedure. In 9, it was a second operation following an unsuccessful iridencleisis, in 15 it similarly followed an unsuccessful trephining, and in 20 cases, it followed two or more previously unsuccessful operations for glaucoma. Forty-five of these cases were followed for at least one year. In 19 cases (or 42 percent) the cyclodialysis was successful, and the patient maintained a normal intraocular pressure for the year (see table 1). Only one of these 19 successful cases subsequently developed an increase of tension greater than 30 mm., the duration of follow up in this case being 2½ years.

In table 2 these cases are classified according to the depth of the anterior chamber. Thus the operation was performed in 16 eyes with deep anterior chambers, of which 14 were followed for one year or more; 10 (or 71 percent)

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

maintained a normal intraocular pressure at the end of the period of observation. Cyclodialysis was performed in 18 eyes with shallow anterior chambers, 12 of which were followed for one year or more. Only five (or 42 percent) had a normal tension at the end of the period of observation. This difference, although not statistically significant, suggests that cyclodialysis may be more effective in eyes with deep than in eyes with shallow anterior chambers.

In the total of 56 cases of chronic primary glaucoma which are here analyzed, the operation in 27 cases was a failure in that the intraocular pressure was not maintained within normal limits for a period of one year. In 14 (or 52 percent) of these, the failure was evident in the first 14 postoperative days, and in 21 (or 78 percent) it was evident in the first postoperative month. At the end of the first postoperative year, 26 (or 96 percent) of the failures had occurred. This suggests that if the operation is not suc-

TABLE 2

EFFECT OF DEPTH OF ANTERIOR CHAMBER IN CHRONIC PRIMARY GLAUCOMA

Anterior Chamber	Cases Followed One Year	Cases with Tension Less Than 30 mm. Hg (Schiotz)	Per-centage
Deep	14	10	71
Shallow	12	5	42

cessful, the failure usually becomes apparent soon after the operation.

Glaucoma following cataract extraction. Cyclodialysis was performed in 53 eyes with glaucoma following cataract extraction, and 39 were followed for a minimum of one year. In 14 of these eyes (or 35.9 percent) the operation was successful in that the tension was still normal at

the end of one year, although in two cases, followed 2½ years, the tension later rose.

In 33 of these eyes cyclodialysis was performed as the initial procedure, and 26 of these 33 eyes were followed at least one year; 10 (or 38.5 percent) maintained a normal intraocular pressure during this period. In 20 additional eyes, cy-

TABLE 3

EFFECT OF DEPTH OF ANTERIOR CHAMBER IN GLAUCOMA FOLLOWING CATARACT EXTRACTION

Anterior Chamber	Cases Followed One Year	Cases with Tension Less Than 30 mm. Hg (Schiotz)	Per-centage
Deep	19	9	47
Shallow	15	4	27

clodialysis was performed as a second operation, the eyes having had at least one previous operation for the glaucoma. Thirteen of these eyes were followed for at least one year. In 4 (or 30.8 percent) the cyclodialysis was successful, and the eyes had a normal tension at the end of this time. This similarity of results suggests that the presence or absence of previous operative procedures may have little effect on the success of cyclodialysis.

These cases are also analyzed according to the depth of the anterior chamber (table 3). Twenty-four of the patients had deep anterior chambers, and of these, 19 were followed for at least one year. At the end of this time, 9 (or 47 percent) still had a normal tension. Twenty-two of the eyes had shallow anterior chambers, and of these 15 were observed for at least one year. At the end of that time, only 4 (or 27 percent) still maintained a normal intraocular pressure. This suggests that cyclodialysis may be more successful in

aphakic eyes with deep anterior chambers than in those with shallow ones.

There were 27 failures in the 53 eyes of this series. Ten (or 37 percent) of these failures were evident in the first 14 postoperative days, and 15 (or 55.5 percent) in the first month. By the sixth postoperative month, 25 (or 92.6 percent) of all failures had occurred. This again suggests that failure of cyclodialysis to maintain normal intraocular pressure is most likely to occur in the first six postoperative months, and that if in-

TABLE 4
INCIDENCE OF COMPLICATIONS

Complication	Eyes Operated on	Number of Complications	Percentage
Anterior-chamber hemorrhage	140	87	62.1
Vitreous hemorrhage	140	8	5.7
Laceration of Descemet's membrane	140	7	5
Hypotonia	140	3	2.1

traocular pressure is maintained at a level of less than 30 mm. Hg for this period of time, it is unlikely to rise at a later date.

In 11 cases of these 27 failures, a second cyclodialysis was done without another intervening operative procedure. In 4 of these (or 36.3 percent), the follow-up period varying from three months to three years following the last operation, the tension was successfully controlled. In the remaining seven eyes, the second operation likewise was a failure.

Glaucoma secondary to active uveitis. Cyclodialysis was performed in 31 eyes with glaucoma secondary to active uveitis, and all were observed for at least one year. In 16 of these eyes, the cyclodialysis was obviously unsuccessful within the

first 14 postoperative days, whereas in 15, the tension was still normal. At the end of the first postoperative month, eight of these 15 eyes still had a normal tension, and this was maintained in six at the end of three months. However, at the end of one year only two of these (or 6.5 percent of the original cases) had a tension less than 30 mm., whereas 29 (or 93.5 percent) had an intraocular pressure of more than 30 mm. Hg (Schiotz). Each one of these 29 cases subsequently required another operative procedure for the persisting glaucoma. This strongly suggests that cyclodialysis is not effective as a procedure to give any lasting control of glaucoma secondary to uveitis.

COMPLICATIONS

The most frequent early complications of cyclodialysis were anterior-chamber hemorrhage and vitreous hemorrhage. Anterior-chamber hemorrhage occurred in 87 of 140 eyes operated on, an incidence of 62.1 percent (table 4). There was little difference in the incidence in the three types of glaucoma involved. Hemorrhage usually occurred at the time of operation (52.9 percent), but was occasionally seen first at the time of the first dressing (6.5 percent). In the later postoperative course, hemorrhage was uncommon, being present in only three eyes (2.1 percent).

Fifty-six cases of chronic primary glaucoma and 53 cases of glaucoma following cataract extraction were analyzed according to the severity of anterior-chamber hemorrhage (tables 5 and 6). Of the 56 eyes with chronic primary glaucoma, 36 eyes had either no hemorrhage or one occupying less than one fourth of the anterior chamber. Twenty-eight of those eyes were followed for at least one year. At the end of that time 15 (or 54 percent) had a normal tension. Twenty eyes were observed with hemorrhages oc-

cupying more than one fourth of the anterior chamber. Sixteen of these were followed for at least one year, and in only 4 (or 25 percent) was a normal tension present at the end of this period. This suggests that hemorrhage occupying more than one fourth of the anterior chamber may predispose to failure of the operation. The same holds true in aphakic eyes. Of the 53 cases in this group, 40 had either no anterior-chamber hemorrhage or one occupying less than one fourth of the chamber. Twenty-eight of these cases were observed for at least one year, and at the end of that time, in 12 (or 43 percent) the operation was successful. In 13 cases hemorrhages occupied more than one fourth of the anterior chamber, and of 11 cases followed at least one year, only 2 (or 18 percent) maintained a normal tension. In one case, the anterior-

eyes was there any final reduction of vision attributable to the hemorrhage.

Two late complications of cyclodialysis encountered in this series were hypotonia and lacerations of Descemet's membrane. Hypotonia occurred in three of 140 eyes

TABLE 6

EFFECT OF ANTERIOR-CHAMBER HEMORRHAGE ON THE CONTROL OF GLAUCOMA FOLLOWING CATARACT EXTRACTION

Amount of Hemorrhage	Cases Followed One Year	Cases with Tension Less Than 30 mm. Hg (Schiotz)	Percentage
None, or less than one fourth of anterior chamber	28	12	43
One fourth or more of anterior chamber	11	2	18

TABLE 5

EFFECT OF ANTERIOR-CHAMBER HEMORRHAGE ON THE CONTROL OF CHRONIC PRIMARY GLAUCOMA

Amount of Hemorrhage	Cases Followed One Year	Cases with Tension Less Than 30 mm. Hg (Schiotz)	Percentage
None, or less than one fourth of anterior chamber	28	15	54
One fourth or more of anterior chamber	16	4	25

chamber hemorrhage resulted in occlusion of the pupil.

Vitreous hemorrhage occurred in 2 of 56 eyes with chronic primary glaucoma, in 6 of 53 eyes with glaucoma following cataract extraction, and not at all in 31 eyes with glaucoma secondary to uveitis. This represents an over-all incidence of 5.7 percent. In only one of these eight

operated on, an incidence of 2.1 percent, but in no instance resulted in a decrease of final visual acuity. Lacerations of Descemet's membrane occurred in seven of 140 eyes operated on, an incidence of 5 percent, but again in no case did it result in a reduction of final visual acuity.

DISCUSSION

A survey of the literature reveals varied reports of the final results obtained following cyclodialysis. These range from 28 percent reported by Meissner and Sattler² to 77.8 percent reported by Gradle.³ The latter's results were obtained in cases of chronic simple glaucoma with no inflammatory reaction. Comparable results were obtained in this series in a group of cases similar to Gradle's, those with chronic primary glaucoma and deep anterior chambers. Spaeth reports cyclodialysis to be successful in 45 to 50 percent of cases.⁴ His series included, in addition

to cases of chronic primary glaucoma, cases of inflammatory glaucoma and those in which other operations for glaucoma had been performed. Similar results were obtained in the present series in that group of cases which included all types of chronic primary glaucoma. It seems that probably the best results would be obtained in primary glaucoma by adhering to Gradle's dictum and performing cyclodialysis only in chronic simple glaucoma without inflammatory reaction.⁵

The widely accepted belief that cyclodialysis is a harmless procedure is given further proof in this series; for, in spite of an incidence of anterior-chamber hemorrhage of 62.1 percent and of vitreous hemorrhage of 5.7 percent, only two of 140 eyes operated on showed any reduction of vision as a result of these complications. In addition, there was no instance of postoperative infection.

The low incidence of success in glaucoma secondary to active uveitis, the low incidence of success in eyes with shallow anterior chambers, and the poor results obtained after severe anterior-chamber hemorrhage point to some obstruction of the angle of the anterior chamber as the probable cause of failure of the procedure. If one accepts Barkan's conclusion that the establishment of a communication between the anterior chamber and the suprachoroidea is a mechanical *sine qua non* in the successful action of cyclodialysis, it is easy to understand the failure in these cases.⁶

Because of the relative frequency of anterior-chamber hemorrhage and its untoward effects on the prognosis following cyclodialysis, various procedures to prevent hemorrhage were made at operation. These include cauterization of episcleral vessels prior to scleral incision, pressure over the sclera during withdrawal of the spatula and for a short time thereafter, and the use of the Randolph spatula to ir-

rigate the chamber once hemorrhage has occurred. The relative efficacy of these measures was impossible to evaluate.

SUMMARY

The results of cyclodialysis in 140 eyes with chronic primary glaucoma, glaucoma following cataract extraction, and glaucoma secondary to uveitis are analyzed.

(1) Cyclodialysis resulted in an intraocular pressure of less than 30 mm. Hg (Schiotz) in 42 percent of 45 cases with chronic primary glaucoma, in 35.9 percent of 39 cases with glaucoma following cataract extraction, observed for one year, but only in 6.5 percent of cases of glaucoma secondary to active uveitis.

(2) Cyclodialysis was more effective in eyes with deep than with shallow anterior chambers in both chronic primary glaucoma and glaucoma following cataract extraction.

(3) Failure of cyclodialysis to maintain intraocular pressure at less than 30 mm. Hg (Schiotz) was most likely to be evident in the first postoperative month, 78 percent of the failures in chronic primary glaucoma, and 55.5 percent in glaucoma following cataract extraction being noted in this period. Practically all failures occurred in the first year; 96 percent of those in chronic primary glaucoma and 92.6 percent of those in glaucoma following cataract extraction.

(4) In glaucoma following cataract extraction, after the failure of one cyclodialysis to control tension, a second cyclodialysis was successful in 36.3 percent of 11 cases so treated.

(5) Anterior-chamber hemorrhage occurred in 62.1 percent of 140 eyes operated on. Hemorrhage occupying more than one fourth of the anterior chamber prejudiced the control of intraocular pressure in eyes with chronic primary glaucoma and in those with glaucoma follow-

ing cataract extraction, but smaller hemorrhages had no deleterious effect.

(6) Vitreous hemorrhage occurred in 8 of 140 eyes operated on, an incidence of 5.7 percent. In only one case was there a reduction of vision directly attributable

to the vitreous hemorrhage.

(7) Postoperative hypotonia was encountered in 2.1 percent of 140 cases and lacerations of Descemet's membrane in 5 percent. In no case did these result in a reduction of final visual acuity.

UNAIDED VISUAL ACUITIES CORRELATED WITH REFRACTIVE ERRORS

A STUDY

MORRIS H. PINCUS, MAJOR (MC), A.U.S.

INTRODUCTION

With the passage of the Selective Service Act, in 1940, and especially after the attack on Pearl Harbor by the Japanese, many men and women, the volunteers as well as those who were called to serve their country, came to the Army Induction Stations and General Dispensaries for their physical examinations.

These centers were overtaxed with applicants. Complete and impartial physical examinations had to be conducted with the meager means at hand, and opinions had to be given regarding the fitness or unfitness of the individual for military duty. Sometimes these opinions were made hurriedly, sometimes under extreme pressure.

The ocular examinations came to be regarded as of great importance. Many applicants who desired to enter the military service tried to hide visual defects, either by not mentioning them or by attempt-

ing to evade their detection. A few who wished to evade military service entirely as well as those anxious to obtain a non-combatant classification exaggerated a known visual defect or stated that one existed.

It is pertinent to mention these two groups—negative and positive ocular malingerers—because the writer found that their existence created a very definite need for some systematized method of correlating the unaided visual acuity with the refractive error, provided the correcting lenses brought the visual acuity of the eyes to the accepted Snellen standard of 20/20, when no organic disease was present.

For example: If three individuals possessing correcting lenses of $-1.50D.$ sph. $\approx -1.00D.$ cyl. ax. 180° , which gave them normal vision, presented themselves for examination, and the unaided visual acuity of one was 20/200, of the sec-

ond 20/100, and of the third 20/300, an average uncorrected visual-acuity reading of 20/200 would be obtained. It would then be reasonable to expect an unaided visual-acuity reading in the vicinity of 20/200 from others who possessed correcting lenses of that power, provided no organic ocular lesion was present.

As has been stated, the unaided visual acuity of any group of persons who possess the same corrective power of lenses would vary. Numerous factors—such as age, fatigue, foci of infection, malnutrition, accommodative power—would cause such variations, but there would be a reasonable range of such variation.

A chart or charts containing the average unaided visual-acuity data and the visual ranges for each of the corrective lenses most commonly encountered would materially aid an examiner in the detection of malingerers, and in classification.

The opportunity for such study presented itself in two ways. The great majority of the men and women who came for the physical examination prior to induction to the service were applying as officer candidates. The general average-intelligence level of these people was somewhat above that of the average inductee, and their responses during the ocular examination were somewhat more reliable. This, however, does not exclude a considerable portion of this group from the two classes of ocular malingering mentioned previously. Secondly, when the Army began to issue spectacles to its personnel, requests for refractions increased by leaps and bounds. The officers and enlisted men presenting themselves for an ocular examination and refraction, as a whole, no longer had any reason to be positive or negative malingerers. Many came because they were told that they needed glasses; a number came because they thought that this was a good oppor-

tunity to have their spectacles changed; others, because they desired an ocular examination.

METHODS

The physical-examination records of 45,206 men and women as well as 7,482 refraction records were reviewed for this study. Since each square of the presented charts represents the unaided visual acuity of an eye that obtained standard vision with the corresponding correcting lens or lenses, all records that showed vision correctable to 20/20 in the absence of organic disease were retained for tabulation.

All of the examinations were performed at an Army General Dispensary. The author personally examined more than half of these individuals, and the remainder were examined by associates trained in his routine methods of examination.

Each examinee, whether present for a routine physical examination or for an ocular examination and refraction, was impressed with the fact that squinting would not be permitted.

The American Optical Company Projecto-Scope and Screen were used throughout these examinations. Visual acuities were tested at 20 feet from the screen. The unaided visual acuity of each eye as well as binocular vision was recorded. Individuals who had unaided visual acuity of less than 20/400 in one or both eyes, were slowly walked up to the 400 figure until it was accurately identified. The distance between the examinee and the screen was then recorded as the numerator and 400 as the denominator. No one chart or figure was used consistently. Four different Projecto-Scope charts were used interchangeably, so that no one could familiarize himself with nor memorize them.

Each eye was then examined for patho-

logic lesions and a notation made of any existing abnormality. Following this, the spectacles (if any) of the examinee were neutralized, and the vision of each eye, separately, and the binocular vision with the glasses were noted. If the vision in each eye was not corrected to 20/20, a rapid retinoscopic examination was performed with the aid of the trial-case frame and lenses. The best visual acuity obtained for each eye and the strength of the correcting lenses in the trial-case frame were recorded on the physical-examination sheet. Fundus studies were made on all whose vision in either eye was not correctable to 20/20; on all whose unaided visual acuity was 20/100 or worse; and on all who gave a history of ocular pathologic change.

All military personnel under the age of 40 years, with no contraindications noted, received a cycloplegic examination. The manifest refraction of those over 40 years was recorded. Fundus studies were made in every instance.

METHOD OF TABULATION

Fifty charts for each refractive group, exactly as those presented, were attached to a large board. The upper row represented the Hyperopic group, the middle row represented the Myopic group, and the lower row the Mixed-Astigmatism group.

As each record was reviewed, the refractive error was noted, and the square corresponding closest to that error was filled with the unaided visual acuity, and the age of the individual. As the squares of the lower refractive errors quickly filled the 50 charts of each group, additional charts were attached in order to include all such unaided visual acuities.

With the review of records completed, loose-leaf pages, each marked consecutively to correspond to the refractive errors, were made up in book form—one

book for each refractive group.

Each page had the refractive error, age groups, and axes arranged in the manner shown in table 1. The recorded unaided visual acuities were then transposed to the proper pages and inserted under the correct age-group and axes columns.

These columns were individually added, and the total divided by the number of figures in that column. This gave the average unaided visual acuity for that particular refractive error and age group. Immediately below each column the extremes of unaided visual acuity were recorded and enclosed in parentheses.

Since the average unaided visual-acuity figures are impracticable for use by the average examiner, the writer converted them to the nearest Snellen equivalent.

For example: In table 1 the average unaided visual acuities are: 35, 32, 38, 37, 44, 41, 52, 50, 52, 49, 61, 57. When converted to the nearest Snellen equivalent they become: 30, 30, 40, 40, 40, 40, 50, 50, 50, 60, 60, 60.

RESULTS

Table 2 represents the average unaided visual-acuity findings of eyes, with no organic pathologic lesions which are correctable to 20/20 by the corresponding lens corrections in the three main refractive-error groups.

The great majority of the unaided visual-acuity readings are accounted for in the triangular region of 0 to 4.00D. spheres and 0 to 3.00D. cylinders, singly, and in combination, in all refractive groups. Myopic corrections predominated. The vacant spaces noted appear particularly in the oblique-axis columns and signify that these corrective lenses were not encountered in this study.

The unaided visual acuities under the oblique-axis cylinder corrections are, as a rule, slightly less than those found under the horizontal or vertical meridians.

As the average age in the Hyperopic group increased, the average unaided visual acuity for the same correcting lenses became increasingly worse. This is physiologic and to be expected.

The age factor in the Myopic and in the Mixed-Astigmatism groups, apparently does not materially influence the results of the unaided visual acuity for the same correcting lenses.

nately, the methods of recording visual acuity are not uniform. Many letters of affidavit for applicants testify to such lack. Many ocular prescriptions for spectacles from military installations brought similar evidence.

To obtain a proper record of visual acuity the head and eyes of the examinee must squarely face the chart. No squinting, head tilting, nor turning must be per-

TABLE 1

.35			37		41				49		57
	32										
(30-50)	(25-40)	(30-50)	(30-50)	(40-50)	(30-50)	(40-70)	(40-70)	(40-70)	(40-70)	(50-100)	(50-70)

Figures 18-29, 30-39, 40+, represent the different age groups.

Figures 1, 2, 3, 4, represent axes 45, 90, 135, and 180, respectively.

The average unaided visual acuity is recorded at the base of each column.

Each figure represents the denominator of the Snellen fraction; 20/.

The figures in parentheses represent the range of unaided visual acuity.

* The figures in each column represent but a fraction of the actual number tabulated for this refractive error.

The average unaided visual acuity of the Mixed-Astigmatism group, as a whole, was much better than that found in either of the other two groups.

In all groups, the average unaided visual acuities became worse as the refractive power of the correcting lenses increased.

As an interesting feature in this study, it was noted that Mixed-Astigmatism occurred more frequently in women.

COMMENT

Visual-acuity records, for the ophthalmologist, for the patient, and for statistics, are exceedingly valuable. Unfortu-

mitted. The vision should be tested both with and without glasses, provided glasses are worn, and the monocular as well as the binocular vision noted in each instance.

The Army physical-examination requirements specifically state that if the vision is within such and such range and correctable to such and such a value the individual will be classified thus, and so on. Any number of applicants are borderline problems, and an examiner is hard pressed to determine with a clear conscience just how to classify these individuals.

This study was undertaken because a need was felt for some simple expression

[illegible]

by which an examiner could rely on the answers given. Such information would be of value not only for mobilization and demobilization purposes, but for certain phases of civilian life as well.

Only eyes free from organic defects and with vision correctable to the accepted Snellen standard of 20/20 within the range of 0 to 6.00D. spheres and 0 to 6.00D. cylinders, in half-diopter increases, singly and in combination, in all three refractive-error groups, were selected for this study.

Thorington,¹ in his book on refraction, stated, "The visual acuity under definite conditions is an index of the strength of the necessary spherical lenses (plus or minus) which will give a vision of VI/VI or more. For instance, the question which has been decided is this: If a healthy eye, Hyperopic or Myopic, without astigmatism (or an eye with its astigmatism corrected with a cylinder) has the ability to see VI/VI, and has its ciliary muscle under the effect of 'drops,' what strength spheric lens would be required to give it normal vision? To begin with the writer had to work backward, so to speak, and in the following manner: The eyes were tested at six meters, and with the lenses which gave standard vision the eyes were tested to find out what the visual acuities would be when plus spheres were placed in front of the correcting lenses."

Agatston,² in his paper on "Ocular malingering," presented a table on the correlation of uncorrected visual acuity with the refractive error for myopia, myopic astigmatism, and compound myopic astigmatism based on the results of experiments with six Army men. "These subjects, each with less than 1 diopter of refractive error, had full correction, and, one eye being used at a time, the various refractive states were simulated by employment of plus lenses at the anterior fo-

cal plane. . . . If necessary, the examiner, using himself as a subject, may properly simulate any refractive error he may encounter."

In both instances, simulation was the method chosen. Though the conclusions are noteworthy, they were based on too few observations.

The author, with the help of his assistant, did simulate the different refractive errors. It was soon apparent, however, that no matter how truthful he attempted to be, he could not avoid recognizing figures or numbers which were blurred, and which would, no doubt, be unrecognizable to an individual whose unaided visual acuity was correctable to the normal value by the corresponding refractive corrections used.

In this study the recorded unaided visual acuities of more than 50,000 individuals, men and women, of different age groups were correlated with the refractive errors.

The great majority of the unaided visual-acuity readings were encountered in the region of 0 to 4.00D. spheres and 0 to 3.00D. cylinders, singly, and in combination, in both the Hyperopic and Myopic refractive groups. These average unaided visual-acuity readings are highly accurate. Beyond the 4.00D. spheres and 3.00D. cylinders, singly, and in combination, fewer readings for these corrective powers were obtained. Though fairly accurate, they do not possess the high degree of accuracy noted for the corrective-lens combinations mentioned previously. The empty spaces noted occur particularly in the oblique-axis columns and signify that such refractive errors were not encountered in this study. They could, however, be filled by interpolation. Other studies of this character, made on greater numbers of individuals, would help to fill these blank spaces and to corroborate

the work which has already been accomplished.

Armed with such information, an examiner would be aided materially in the detection of malingerers. It would help in classification and assignment of individuals entering the service. Many individuals will, no doubt, claim compensation for visual impairment aggravated by the stress and strain of war. Except for those with traumatic or organic pathologic lesions of the eyes, the truth or falsity of such claims in subjects who have unaided visual acuities correctable to 20/20, with lenses, the refractive power of whose eyes had not changed, would be readily determined. Positive malingerers will, of course, be tested with other corroborative methods.

In certain phases of civil life—for example, in the case of compensation work, civil suits, insurance—such information can be of great value.

Similar charts for the Navy can be constructed by using the Conversion Formula of Allen.³

CONCLUSIONS

A study, correlating the unaided visual acuities with the different refractive errors, obtained from a review of more than 50,000 physical examination and refraction records at an Army General Dispensary, is presented.

Only eyes free from organic defects and correctable to 20/20, within a range of 0 to 6.00D. spheres and 0 to 6.00D. cylinders, singly, and in combination, in all three refractive-error groups, were selected for tabulation.

This study was undertaken because a need was felt for some simple expression by which to determine and confirm the truth or falsity of answers given by applicants during the ocular examinations.

The importance of this study is reflected in the fact that, armed with such information, borderline individuals could be properly classified, and malingerers detected. Such information is of practical value not only for mobilization and demobilization purposes, but for certain phases of civilian life as well.

NOTES, CASES, INSTRUMENTS

A METHOD OF EVISCERATION OF THE EYEBALL*

RALPH W. DANIELSON, M.D. AND
JOHN C. LONG, M.D.

Denver, Colorado

From time to time for many years articles have appeared on the subject of enucleation as compared to substitute operations. For a detailed discussion of the indications and contraindications for each, one may find an excellent portrayal of the subject in the American Encyclopedia of Ophthalmology for 1915¹ and in articles by Burch,² Guibor,³ and very recently in the published report of the symposium by Gradle,^{4a} O'Brien,^{4b} Kirby,^{4c} and Pfeiffer^{4d} at the 1944 session of the American Academy of Ophthalmology and Otolaryngology. Spaeth⁵ discusses the question in his book. Weigelin⁶ wrote on the subject in World War I.

We shall refer to only a few of the numerous variations in surgical technique in performing eviscerations. Gifford⁷ in 1900 reported 14 cases of simple evisceration (leaving the cornea) and favored this above the ordinary evisceration which is combined with keratectomy. In his operation, Gifford made a meridional incision three fourths of an inch long through the sclera midway between the external and superior recti, extending from within 3 mm. of the corneal margin toward the posterior pole of the eye. The contents of the eye were then scraped out through this incision, which was held apart with hooks or forceps. The scleral shell was collapsed by inserting gauze beneath the lids. Gifford stated that he had much less postoperative edema when he had used this method than after following

the ordinary procedure for evisceration.

In a subsequent paper, Gifford⁸ redescribed his evisceration technique. He believed that the Mules operation gave the best cosmetic result, but thought that the pushing of the anterior half of the eye into the posterior half was almost as good. Grimsdale and Brewerton⁹ have discussed evisceration technique in detail. Burch² has urged evisceration with preservation of the cornea. Others, including Huizinga,¹⁰ have recommended making an opening in the sclera posteriorly to permit drainage of fluid from the scleral cavity.

Burch,² in discussing his method of evisceration, advises as additional safety factors the wiping off of the endothelium from the cornea and the application of iodine to the scleral cavity, followed by cocaine neutralization and by irrigation. Other authors have recommended other chemical treatments of the cavity.

Potechina¹¹ reported a scleral cyst following evisceration of the eye. Mahoney¹² says he favors evisceration in many cases, but does not favor it if there is injection of the ciliary body, even if the surgery is done promptly after an injury.

Dimitry¹³ describes his evisceration technique in which he (1) cuts off the cornea and the sclera, including the ciliary-body region; (2) cuts out a piece of the sclera posteriorly, including a piece of the optic nerve; (3) implants a ball; and (4) makes V-shaped cuts in the sclera to allow it to fit more snugly over the gold ball. This is a modification of the Mules¹⁴ operation.

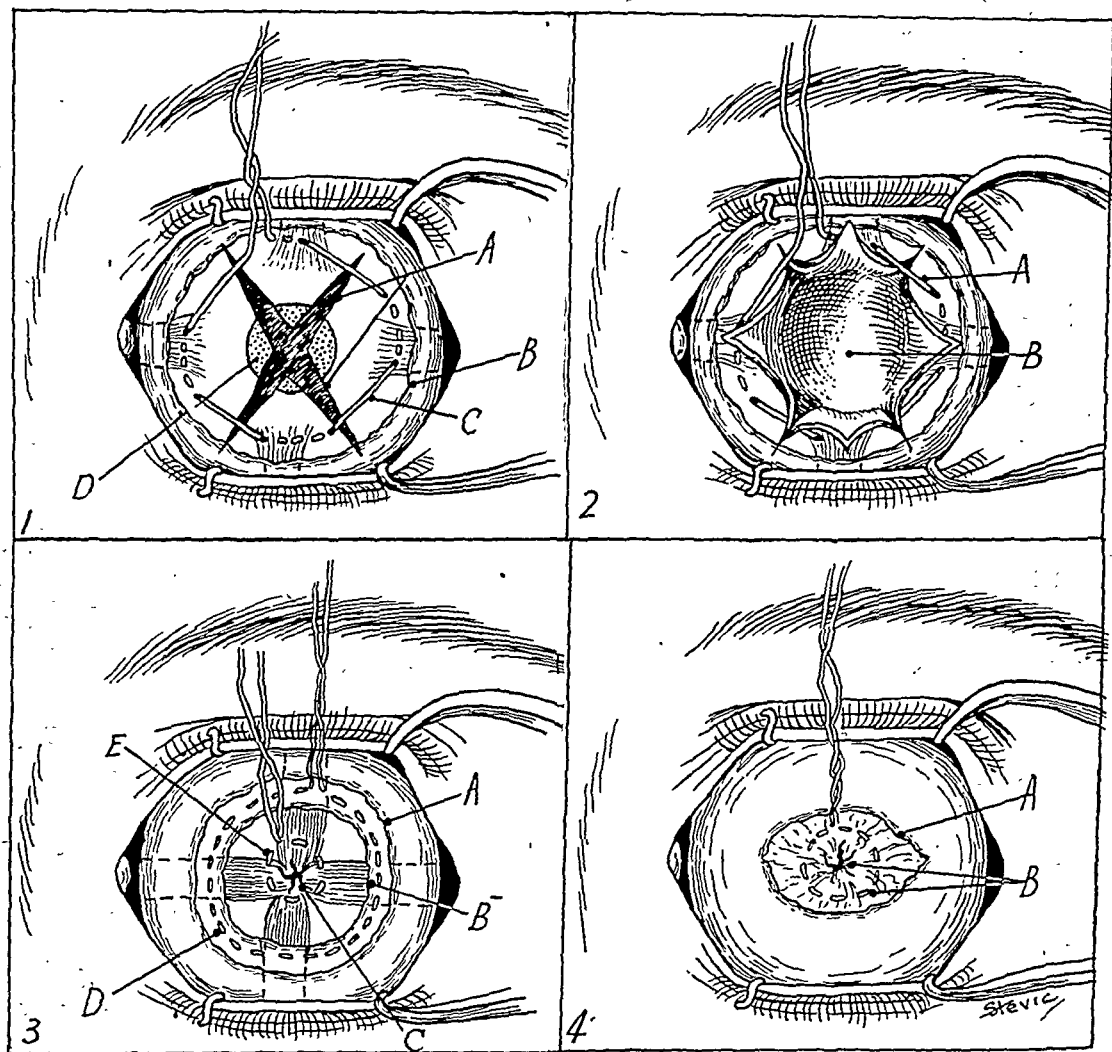

O'Connor,¹⁵ in 1930, described a technique of evisceration quite similar to the one which we have independently employed.

Several years ago, when confronted with a case of gross corneal laceration

* From the University of Colorado School of Medicine.

with extrusion of the scleral contents, the authors decided to perform an evisceration in a somewhat unconventional man-

to collapse in the following manner: The corneal and scleral lacerations were enlarged and supplemented by additional in-

Figs. 1-4 (Danielson and Long). Steps in performing evisceration. Fig. 1, appearance of eye with incisions made but lips almost closed. A, incisions in cornea and sclera; B, edge of conjunctiva; C, purse-string suture; D, cornea. Fig. 2, appearance of eye with lips held open and evisceration completed. A, purse-string suture; B, showing everted, cleaned sclera. Fig. 3, appearance after invaginating anterior lips into posterior portion by tying first purse-string suture. A, edge of conjunctiva; B, edge of Tenon's capsule; C, dimpled, inverted center; D, 2d purse-string suture; E, 1st purse-string suture. Fig. 4, appearance after both purse-string sutures are tied, before closing conjunctiva. A, edge of conjunctiva; B, position of first and second purse-string sutures.

ner. We had previously noted cases of evisceration with keratectomy in which the sclera remained for a considerable period as an open, secretion-filled cup. To avoid this difficulty, the sclera was made

cisions back to the equator. A purse-string suture was inserted about the equator, and the anterior portion of the eye was then invaginated into the posterior half and the sutures tied. A second purse-string

suture in Tenon's capsule combined with conjunctival sutures closed the wound. The result was excellent, and the technique has since been used on several occasions very satisfactorily.

The following steps are taken in performing the operation:

1. Circumcision of the conjunctiva at the limbus and retraction of conjunctiva and Tenon's capsule.

2. Four or more incisions, or extension of lacerations, of the cornea and sclera back to or somewhat beyond the equator (fig. 1).

3. Evisceration of contents of globe with curette and gauze. A small suction tip is of value in keeping the field clear. One must wait for complete hemostasis. Some surgeons might wish to treat the interior chemically (fig. 2).

4. Placing of chromic catgut sutures in the sclera.

5. Invaginating the anterior sections into the posterior portion (figs. 3 and 4).

6. Interrupted plain 5-0 catgut closure of conjunctiva.

7. Pressure bandage with adhesive which is allowed to remain from two to three days before changing.

The advantages of this operation are:

1. The sclera acts as the implant. 2. The interior can be thoroughly cleaned. 3. The recti muscles are connected with the implant. 4. The healing is rapid. 5. The final

cosmetic result is excellent. 6. Patients may be up and about and out of the hospital the day after surgery if necessary, especially if a pressure bandage is applied. 7. No implant to be extruded.

This operation seems particularly suited to cases of severe laceration of the anterior segment. It can also be used in painful eyes such as ones with absolute glaucoma or in those removed for cosmetic reasons. In these latter cases the first purse-string suture could be inserted before the eyeball is opened.

This type of evisceration is contraindicated in cases of acute endophthalmitis, for thereby organisms may be introduced into the peribulbar tissues. The operation can probably be safely done in cases of long-standing endophthalmitis because of a decrease in the virulence of the infection and a partially acquired immunity to the offending organisms. It would seem to be good practice to administer penicillin and sulfonamides in all cases in which the possibility of infection exists.

SUMMARY

The literature of the last 30 years on methods of evisceration has been reviewed briefly.

A method of evisceration, very similar to the one of O'Connor, is described.

324 Metropolitan Building (2).

SCLEROMALACIA*

FREDERICK A. KIEHLE, M.D.†

Portland, Oregon

At the meeting of the Academy of Ophthalmology and Otolaryngology held in New York City in 1936, I reported under the above title¹ the case of a woman, then 64 years of age, who had been the victim of rheumatism for 21 years.

At the time of her death, last October, she had been bed-ridden for 18 years with deforming arthritis.

Both eyes had been completely immobile for the preceding five years, fixed in the primary position. She was wasted to a skeleton. Her spine was rigid. There had been only perception of light for some years. Ocular pain was never intense, and rather best described as a burning sensation. This could be relieved by mild ointments. In the early stages of her condition the retinas could be seen, but evinced no pathologic change. The vitreous was clear. For a long time, however, the corneas had been opaque. It was assumed that tension was normal, although application of a tonometer was inadvisable. On autopsy it was found that all

extrinsic muscles were degenerated and reduced to mere cords. Absorption of the sclera had advanced well beyond the equator. There was in each eye an adhesion of the bulbus to the upper lid. Although no perforation of the sclera could be demonstrated, it is probable that perforation had occurred, thus accounting for the adhesion of the bulbus to the upper lid and bringing the case under Van der Hoeve's classification of scleromalacia perforans. (Van der Hoeve stated² that one of his cases had been under observation for 40 years before perforation took place.)

On enucleation of the right eye, the sclera, exceedingly thin throughout in each eye, was punctured at this point of adhesion. The vitreous was like water and entirely escaped. Even greater care was exercised in removing the left eye, and at the point of attachment to the upper lid a segment of tarsal conjunctiva was included. Thus the bulbus was removed intact. Both eyeballs seemed enlarged.

Pathologic diagnosis (report by Army Medical Museum): Scleromalacia (perforans?). Chronic active iridocyclitis.

"A (left eye). Behind the equator the sclera appears fairly normal; at the insertion of the recti muscles the fiber bundles are broken, the sclera becomes thin-

†Professor emeritus of Ophthalmology.

ner and almost disappears over the ciliary body. The iris and the ciliary corona are diffusely infiltrated with chronic inflammatory cells, most of them of the lymphocyte series. Eosinophiles are fairly numerous and Russell bodies are present. The iris is stretched and somewhat attenuated by adhesions of the pupillary border to the cornea. The cornea is thin, irregular in width, vascularized. Bowman's membrane is absent, and the anterior lamellae are infiltrated with chronic inflammatory cells. The corneal epithelium is thickened, and irregular in width; Descemet's membrane is thick.

"The lens is not in place but was sectioned separately. It is small, irregular in outline, the anterior capsule wrinkled, and beneath it is a large amorphous deposit containing calcium granules. The capsular epithelium has disappeared in the center of the anterior surface over the amorphous deposit.

"B (right eye). This globe is partially collapsed (artefact); otherwise the picture is similar to the other eye. There is greater destruction of the sclera; the cellular infiltration of the cornea is slightly less marked; and the iris involvement more extensive. There are peripheral anterior synechiae as well as pupillary ones. In the pupillary area are pink masses adherent to the anterior and posterior surface of the iris, which appear to be hyalinizing scar tissue but may represent lens remnant. The cross section

of the optic nerve of this eye shows a sector of atrophy."

As a further contribution to the subject I quote from a letter from Sir Stewart Duke-Elder, who writes: "The patient with scleromalacia whom I saw in March was a woman of 56 who had been suffering from polyarthritic rheumatism for about 30 years, and is now a complete cripple with most of her joints ankylosed. The right eye showed two large areas over which the sclera had completely disappeared, exposing the uvea, and in the left eye, all around the ciliary region, a similar condition existed, there being only one or two bands of sclera remaining. In the left eye there was a circular ulcer all round the cornea, of an atrophic indolent type. Nothing in the picture suggested inflammation.

"I am proposing to do a mucous membrane graft from the lip to cover the exposed areas sometime in the near future.

"Apart from the very few references quoted in the second volume of my textbook I know of no more recent publications on this very rare condition. You can quote anything of this you like."

Thus little by little may be gathered together the facts having to do with this unusual condition. There is undoubtedly a connection between scleromalacia and deforming arthritis. It is to be hoped that this relationship can be established and explained.

EPIDERMOID CARCINOMA OF THE CORNEA

ARTHUR J. BEDELL, M.D.
Albany, New York

This condition is not extremely rare. There are, however, comparatively few reports in the current literature and still fewer that combine photographs and the pathologic report.

A man, aged 74 years, gave a history of a corneal disease which started 18

Fig. 1 (Bedell). Epidermoid carcinoma of the cornea. Left eye. Umbilicated, rough, nodular tumor mass covering the entire cornea.

years before I first saw him. He said that in the beginning there was a small spot on the side of "the clear part" (the cornea) of his left eyeball. He saw a physician, but no treatment was advised; so, during all of these years, he sought no further counsel, although from time to time the eye bled for a few days. He was conscious that his sight was steadily diminishing, and for the past several months knew that he was blind in that eye. He definitely stated that he had never had pain.

The right eye was essentially negative. With a correcting lens the vision was 20/20. There were no external evidences of inflammation and no fundus alterations.

The left eye was blind, the eyelids were free, the eyelid borders were not congested, the cilia were normal in number and size. The conjunctiva was only slightly injected near the junction of the inner canthus and lower lid. The entire cornea was an elevated, vascular mass with umbilication near the center (fig. 1). The surface was rough, lobulated, and nodular. There was a very narrow, crescentic extension beyond the nasal limbus; otherwise the bulbar conjunctiva and sclera were uninvolved. There were several fine vessels and an occasional larger one in and on the pale-pink friable tumor, which was several millimeters thick. A thin, mucopurulent discharge was adherent to the surface of the growth.

The patient was advised to have the eye enucleated. Following the operation he made an uneventful recovery.

The eyeball was sent to Dr. T. L. Terry of Boston, whose report follows:

Pathologic diagnosis. Epidermoid carcinoma, Group II, involving the cornea.

Microscopic description. At the level

Fig. 2 (Bedell). Epidermoid carcinoma of the cornea. Profile section showing the irregular surface, variable thickness, and neoplastic extension over the nasal limbus.

at which the sections were made, the entire cornea is covered with a relatively thick epidermoid carcinoma, Group II. In some places, the tumor is 3 mm. thick.

Its surface is irregular (fig. 2). Carried with it is a moderately large amount of stroma which contains a somewhat irregular distribution of blood vessels (fig. 3). In some places, the stroma is relatively vascular; in others, it appears almost avascular. Bowman's membrane has

vascularization is in the more superficial parts. Mesenchymal epithelium is absent in places. The iris angle is open, and the ciliary processes show some hyalinization. The lens cortex contains a few acidophilic vacuoles. The retinal separation appears to be a post-mortem change.

Fig. 3 (Bedell). Epidermoid carcinoma of the cornea. Low-power magnification, $\times 55$.

been eroded and destroyed over relatively large areas. At the central portion of the cornea, however, some Bowman's membrane is seen to be still present. The tumor does not appear to have gone into the substantia propria at any place. The cornea is infiltrated with wandering cells rather irregularly, some of which have taken on a flattened shape like corneal corpuscles (fig. 4). There is also some vascularization of substantia propria;

The photograph of the gross specimen shows the discrete and confluent nodules which are clearly distinguished by the differences in level.

On section, the tumor was found to be confined to the cornea except for a few millimeters beyond the nasal limbus.

This case is presented because of its unusual extent and the fact that it might be mistaken for leprosy and, of course, the reverse holds, that a leproma might

Fig. 4 (Bedell). High-power magnification, $\times 335$. Characteristic cells and grouping.

be mistaken for a malignancy. The latter is improbable on the part of any observant physician, for the corneal leproma is

a late manifestation and the other stigmata of advanced leprosy would be evident.

A photograph of a leproma is presented (fig. 5) to illustrate the practically complete loss of eyelashes, the bulbar conjunctival congestion and the tumor, the surface of which was smoother and not so uniform in thickness as the carcinoma. There was less tendency to bleed, although the vessels were larger than those in the neoplasm. The other eye was also affected for in leprosy both corneas are practically always involved.

A tuberculoma of this size would have other concomitant signs of tuberculosis and local inflammation.

344 State Street.

CHOICE OF GRAFTS FOR ORBITAL RECONSTRUCTION

CHARLES M. MACKENZIE, M.D.

Spokane, Washington

When a graft is necessary to line the orbital cavity in orbital reconstruction, the choice of graft is important.

Since Virchow first suggested that loss of mucous membrane be replaced by skin, the epidermal layer of skin has been used, until recent times, for resurfacing cavities such as the mouth, nose, orbit, vagina, and others, despite the fact that its epithelial cells become macerated, exfoliate, and produce a foul-smelling discharge.

Wolfe¹ was the first to report the success of mucous-membrane transplants, and, following the demonstration of Esser² that free grafts could be successfully applied as a lining to replace mucous membrane of the mouth by placing the graft around a mold or stent (epithelial-inlay grafting), the problem of cavity lining has been somewhat simplified.

The ideal graft in orbital lining is mucous membrane, and the choice of donor site will depend on whether the patient is male or female. Having tried all the available donor sites, I have listed these in the order of their preference: Male—(1) mucous membrane of mouth;

Fig. 2, Same patient as in figure 1. Shows orbital cavity relined with rectal mucosa.

Figs. 1-3 (MacKenzie). Reconstruction of orbit, using lining of rectal mucosa. Fig. 1, Patient as he appeared after several previous attempts at reconstruction. Note the typical depression of the upper lid and the nick in the center of the tarsal cartilage.

Fig. 3, Same patient as in figures 1 and 2. Shows the stent containing the orbital graft in place with eyelids sutured together. The nick in the tarsal cartilage has been corrected, and the normal contour of the upper lid has been restored by a transplant of fascia lata inserted through an incision in the hair line of the eyebrow.

(2) mucous membrane of prepuce; (3) rectal mucosa; (4) nasal mucosa. Female —(1) vaginal mucous membrane; (2) oral mucous membrane; (3) rectal mucosa; (4) nasal mucosa. The nearest ap-

tant because of the tendency of the glandular elements to become modified by change of environment.

The choice of donor site is determined by simple surgical principles; namely, the

Fig. 4 (MacKenzie). Same patient as in figures 1-3, showing end results.

Figs. 5-7 (MacKenzie). Reconstruction of orbit using lining of mucous membrane taken from the prepuce. Fig. 5, Condition prior to operation.

Fig. 7, Same patient as in figure 6. End results.

proach to a completely successful orbital graft, following several previous failures from preferred donor sites, was accomplished in one case with rectal mucosa.

The difference in the glandular character of these various sites is not impor-

source that can supply the tissue which most closely simulates the conjunctiva; that can be removed with least difficulty; and that will cause minimum inconvenience to the patient. Only on rare occasions will the surgeon be called upon to choose between nasal and rectal mucosa. Of

equal importance to the choice of a donor site is the making of an accurately fitting stent.

Dental modeling compound or wax has never met the requirements for orbital impressions because both distort the tissues and offer difficulties in sterilization. These are largely avoided by using the hydrocolloid-impression material with especially designed, water-cooled trays.

More recently the colloid powder, which I autoclave for 15 minutes and mix with sterile water, further simplifies orbital impressions by eliminating the need for the cumbersome, water-cooled trays. The stents are made of clear acrylic (lucitone) and kept in 70-percent alcohol until used.

RETINAL DETACHMENT SECONDARY TO CONGLOMERATE TUBERCLE OF THE CHOROID

REPORT OF A CASE

H. D. HARLOWE, MAJOR (MC), A.U.S.

Solitary or conglomerate tubercle of the choroid is a rare form of ocular tuberculosis. The first descriptions of this condition in medical literature were those of Von Graefe, Jaeger, Manz, Bouchert, Frankel, Haab, Cohnheim, and Weis. The forms described are: (1) choroidal miliary tubercles, (2) granuloma or solitary tubercle. The first is often associated with acute miliary tuberculosis and the second with chronic tuberculosis.

Conglomerate tubercle of the choroid is, as a rule, unilateral; it occurs most frequently in children and is probably secondary to tuberculosis in other parts of the body. According to Zur Nedden, it has occurred in 62-year-old individuals. Examination with the ophthalmoscope reveals it as an intraocular mass, yellowish white in color. Retinal involvement may occur with subsequent retinal detachment. The diagnosis is often diffi-

cult because one must differentiate the tuberculoma from the following pathologic processes: Retinoblastoma or glioma in children, sarcoma in adults, occasional metastatic deposits of carcinoma in the choroid, idiopathic retinal detachment, retinal cyst, and Coats's disease (massive exudates). Enucleation and laboratory confirmation may be necessary in some cases to establish the diagnosis. According to Verhoeff, this condition is inadequately described in textbooks. Recent publications by Berens, Troncoso, and Wolff discuss this subject.

CASE REPORT

A white man, aged 27 years, was admitted to the hospital on August 20, 1944. His previous history included three months' hospitalization for retinal detachment of the right eye of undetermined origin. Prior to the hospitalization, he had complained of impaired vision, severe headaches, and redness of the right eye. Examination revealed a large retinal detachment present in the right eye from the 11- to the 2-o'clock position. The cornea and lens were clear. The disc margins were quite indistinct, and there

was a pale, yellowish-white mass, about one disc diameter in size, in the right inferior temporal quadrant. The tension appeared to be within normal limits. Vision in the right eye was reduced to perception of finger movements. Previously, the patient's visual acuity had been 20/20, O.U. No abnormal findings were discoverable in the left eye.

Laboratory findings. Red blood cells, 4,600,000; white blood cells, 7,500; neutrophils 58 percent; lymphocytes 30 percent, eosinophiles 12 percent (hookworm); hemoglobin, 94 percent. The Wassermann test and urinalysis were negative. Roentgenograms of the skull, sinuses, and chest were within normal limits. Ova of *Necator americanus* were present. Sputum examination was negative for tubercle bacilli. Urinalysis for melanuria was negative.

Treatment and Course. The diagnosis of hookworm was established, and adequate treatment was given. The patient complained of persistent, severe headaches, and a feeling of pressure behind the right eye. Narcotics were necessary to relieve these symptoms. Enucleation was performed on November 7, 1944, because of a possible choroidal tumor. The headaches were somewhat relieved after the operation, but soon returned. On February 27, 1945, the patient received a plastic prosthesis for the right eye. His case was followed for approximately a year after the operation; he still complained of severe headaches that occurred once or twice a week and lasted for one or two days. Repeated roentgenograms of the skull were negative. Neurologic examination was entirely negative. The pathologic diagnosis was: Granuloma, chorioretinitis, possible tuberculosis (Ash).

Intradermal tuberculin tests after the pathologic report was received were posi-

tive to a very weak dilution of old tuberculin. The sections were reviewed by Klien, who commented as follows: "Sections through the chorioretinal lesion show it to be an old hypertrophic type of chorioretinal scar. The granulation tissue seems to contain some epithelioid cells in addition to the rather obvious giant cells, and the still-preserved portions of the choroid have slight round-cell infiltration. This may be a tuberculoma, an assumption rather supported by the findings in the celloiden section. In this section the retinal periphlebitis, the numerous preretinal precipitates, and the mild optic neuritis would fit very well into the picture of a solitary tuberculous lesion in the eye, the retinal manifestations distant from the lesion being an allergic reaction."

COMMENT

A review of the literature by Horning and Lamb included 55 cases of tuberculoma of the choroid. A few cases have since been added. The condition is usually unilateral, but both eyes may be involved. Verhoeff is of the opinion that "Retinal tubercles do not arise by direct metastasis through the blood stream, but are produced by infected cells which have invaded the vitreous."

Burch replied in regard to this case: "I have never felt quite satisfied with a diagnosis of tuberculoma. In a few sections of that title which I have, I have not been able to demonstrate the tubercle bacilli in them, although the diagnosis was made on the usual pathologic findings. In this case the possibility of 'foreign body giant cells' was suggested." Dodds reported a case of tuberculoma in which all the tissues of the eye were involved. Many tuberculous giant cells were present. Direct smears from the enucleated eye failed to disclose any tubercle bacilli. A guinea pig was inoculated with smears from the eye,

and later the acid-fast bacilli were found.

Finnoff stated: "Conglomerate tuberculoma are often fortunately diagnosed as malignant and only correctly diagnosed microscopically after enucleation." The use of graduated tuberculin skin tests may help in the differential diagnosis. Tuberculous lesions may also appear in other organs as well as the eye, especially the brain. The persistent cephalalgia in this case might be explained on that basis.

SUMMARY

1. A case of conglomerate tubercle of

the choroid with laboratory confirmation is reported.

2. The first diagnosis in this case was idiopathic retinal detachment.

3. The eye was enucleated because of a suspected melanosarcoma of the choroid.

4. The final diagnosis was not confirmed until after the pathologic report was received.

5. The tuberculin skin test may at times be of aid in establishing a diagnosis.

6. A correct diagnosis is often difficult to arrive at in these cases.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

ROYAL SOCIETY OF MEDICINE

SECTION OF OPHTHALMOLOGY

February 8, 1945

MR. P. E. H. ADAMS, *president*

Abstracted by permission from the Proceeding of the Royal Society of Medicine (Section of Ophthalmology), 1945, volume 38, number 3, sectional page 25.

INJURY TO THE LEFT EYEBROW ASSOCIATED WITH SEVERE VISUAL LOSS

Mr. E. F. KING presented O. L., a man, aged 35 years. This patient fell up some stairs. He was not unconscious and walked to the hospital where stitches were used to close a lacerated wound of the left eyebrow. His eyes were examined for the first time on January 23, 1945, when he complained that the vision of his left eye had been defective since the accident. He gave no history of previous eye trouble and had never worn glasses.

Vision of the right eye was 6/6. There was early macular degeneration, apart from which the eye was healthy. Vision of the left eye was limited to ability to count fingers in the lower field. There was a stitched, lacerated wound in the outer half of the eyebrow. There was no irregularity of orbital margin; no displacement of globe; and movements were full. No mass was palpable in the orbit. The pupil was very sluggish on direct light stimulation; good consensual reaction. The media were clear. Apart from slight macular degeneration, essentially similar to that present in the right eye, the fundus was normal. The only visual field present was in an area below fixation, extending to the periphery. The X ray failed to reveal any foreign body or

fracture of the orbit or optic canal.

When the patient was examined again on February 2, 1945, there was some improvement in central vision, now approximately 2/60. There was slight relative temporal pallor of the optic disc and considerable extension of the field of vision, which now embraced fixation.

DUANE'S RETRACTION SYNDROME

WING COMMANDER A. J. ELLIOT presented this subject. Duane's retraction syndrome is characterized by deficiency of abduction, partial deficiency of adduction, retraction of the globe when the eye is adducted, oblique movement when adduction is attempted, narrowing of the palpebral fissure during adduction, and deficiency of convergence.

The syndrome was described in detail by Duane (1905) in a report of 54 cases of congenital deficiency of abduction with retraction, 5 of which were bilateral. He observed that the retraction of the globe may vary from 1 to 10 mm. on adduction. He felt that the retraction was due to the inextensibility of the external rectus muscle, which failed to enlongate, and hence the internal rectus muscle could contract only by retraction of the eyeball. In 9 of the 54 cases, the affected eye protruded slightly when abducted. Duane believed that the narrowing of the palpebral fissure was not a ptosis, but that it was due to the contraction of the orbicularis muscle, the closure being effected as much by an ascent of the lower lid as by a descent of the upper lid.

An atypical form of the retraction syndrome is the condition of strabismus fixus in which there may be a fibrosis of both the internal and external recti. Aebli (1933) reported two cases of this syn-

drome in which the internal rectus muscle was fibrous and attached to the globe at the equator.

The etiology of the condition is not certain. It is not likely that it is due to a birth injury, as Gifford (1926) reports a typical case of the retraction syndrome in an individual who was born by normal Caesarean section. White (1944) considers that the condition is a congenital aplasia of the rectus muscle.

No treatment is required if there is binocular single vision in the central part of the field of fixation. In cases wherein a disfiguring squint or diplopia is present, the only treatment is surgical. Most commonly a moderate recession of the internal rectus muscle is indicated. However, the surgical procedure may be varied according to the findings in each case.

THE CORROSION OF SHARP-EDGED OPHTHALMIC INSTRUMENTS

MR. J. FOSTER, MR. C. H. LEMAY, and MR. K. I. JOHNSTONE discussed the extent of the problem.

E. F. Kayser, senior technologist, Gillette Industries, Ltd., has shown that: "Rusting may occur on the roughest part of a cataract knife (the ground zone) before use, when supplied ungreated, and that rust spoils edges (to a variable extent owing to marked variations in grinding) quicker than use."

CORROSION IN STORAGE. Due to atmospheric water, salt, and acid, corrosion occurs on all ungreated knives, and is most marked in operating-theater cupboards, which have a water-vapor tension equal to that of shops, but a temperature 4.1° above them. This can be reduced by silica gel and lime desiccators, careful handling, and mineral grease.

ANTIDOTES TO CORROSION IN STERILIZATION. Rusting is worst on the ground zone, on curved edges, and on high car-

bon steel. Experimental knives and trephines of beryllium bronze proved moderate clinically and substandard by photomicrography.

Hot-air Sterilization is only slightly corrosive and kills spores, but is slow and requires a big outlay on the sterilizer and multiple sets of instruments.

Hot Mineral Oil is noncorrosive and produces complete sterility. It is slow and difficult to remove. If vegetable oil is employed, each heating produces fresh corrosive fatty acids, gummy polymerization, and oxidation products.

Chemical Methods. *Alcohol* is useless, being corrosive (due to acetic acid and aldehydes) and will not kill even *Staphylococcus aureus* at 130°C. in one hour. *Phenoloids* (antiseptol) Post's solutions, "Dettol," do not kill spores and require washing or boiling to remove them prior to operation. *Mercurials* (metaphen) attack aluminum and possibly steel. This is reduced by addition of borax. *Formaldehyde* (Bard-Parker solution, Liquor sterilisans) kills spores, but Burlingame says 1 to 18 hours are needed if organic matter is present. As spores are killed with certainty by formaldehyde among noncorrosive chemical agents, grease may interfere with their action, and most of them require preoperative removal by aqueous washing or boiling. The method is not without disadvantages. Admittedly spore infection is rare, although recorded by Silberschmidt, Ulbrich, and Marchesani, and corrosion is slight where exposure to water is minimal (Post's solutions, Dettol, and liquor sterilisans).

Boiling in Water is a simple, detergent, complete, and rapid mode of sterilization. All spores die in five minutes if 2-percent Na_2CO_3 is added to the water. Although the Na_2CO_3 reduces rusting by its alkalinity, some knives are spoiled in it by only half a minute's boiling (a period lethal to all-vegetative forms). NaOH and

NH_4OH added to the water prevent rusting, but the risks of carry-over are too great. Chlorates, chromates, phosphates, and nitrites reduce rusting. Neutralin, which is used in dental sterilizers, is superior to Na_2CO_3 alone and could be a useful addition to the dipping technique, but it will not preserve cataract knives for five minutes.

High-Frequency sound and electricity are both possible fields for experiments, although the former is more successful with larger organisms (yeasts), and eddy currents would require both inert atmospheres and special controls to prevent a rise above 200°C . and to avoid tarnish and drawn temper.

CORROSION IN DRYING. Knives last longer in Indian clinics owing to the generally alkaline air, immediate use on sterilization, and immediate drying after section by well-drilled theater teams. We should copy them, for slow pre- and post-operative drying may cause rust as much as boiling.

Na_2CO_3 crystals on the blade produce surprising rust effects, and blood saline and Na_2CO_3 may produce a "cell" on the steel where they touch, and local pitting result. The knife blade, being thin, cools rapidly and therefore dries slowly.

ANTIDOTE TO CORROSION. A possible antidote to corrosion in all three stages may be found in AC.10 (surgical) described by C. H. LeMay, B.Sc., of Manchester Oil Refinery Ltd. AC.10, the lightest of a series of anticorrosive products developed as the result of many thousands of experiments, consists of 95 percent of a light petroleum neutral oil and 5 percent of a complex of sodium salts of petroleum sulphonic acids (the inhibitor). Neither the oil nor the inhibitor alone is an effective corrosion preventive. To obtain optimum protection in a given set of conditions of exposure to corrosive attack, both the oil constituent and

the mixture of sodium petroleum sulphonates must be carefully selected and mutually adjusted for compatibility.

AC.10, itself, was not originally prepared for protecting surgical instruments during sterilization; it was selected as the most likely of the existing range to satisfy the special conditions of this type of exposure, and its formula was adjusted to produce the modification known as AC.10 (surgical), referred to below as AC.10 for brevity.

Experiments checked by high-power microscopic examination showed: (1) That a cataract knife (1.55-percent carbon steel) if dipped for 15 seconds in AC.10 can be kept indefinitely in water vapor, or water at room temperature, without rusting. This satisfies storage requirements. (2) That a cataract knife first dipped for 15 seconds in neat AC.10 can be boiled for 55 minutes in a 2-percent w/v solution of $\text{Na}_2\text{CO}_3 \cdot 10 \text{ H}_2\text{O}$ in water in which 2-percent v/v of AC.10 has been emulsified, without corrosion. If it is redipped in neat AC.10 every 15 minutes, it can be boiled without corrosion indefinitely. This satisfies sterilization requirements.

After operation a sufficient film remains on the knife to protect it for a reasonable period before cleaning (15 to 20 minutes); after cleaning, the film should be renewed by dipping for 15 seconds in neat AC.10 before putting the knife away for storage.

The emulsion should be prepared by dissolving the soda crystals in a relatively small portion of the total water (distilled or well boiled), adding the AC.10 slowly, with vigorous agitation, to this concentrated solution to form a coarse, concentrated suspension, which is then added to the remainder of the water. A fine homogeneous emulsion is formed when this mixture is boiled in the sterilizer.

The protection afforded by AC.10 is

due to the inhibitor so affecting the relation between interfacial tensions in the metal-water-oil system that a film of oil—effective even if monomolecular—is always preferentially formed on the metal surface. In the course of sterilization, when the ebullition might interfere mechanically with the film, the special balance of its ingredients comes into play: the hydrophobic long-chain radical of the inhibitor molecules remains anchored in the oil while the polar sulphonogroup is hydrophilic and permits the formation of an emulsion. Each particle of the boiling liquid therefore carries its own quota of AC.10 with it, and if the film on the instrument is disturbed it may be said to be replaced as rapidly as it is removed.

The effect of emulsifying AC.10 in the soda solution on materials other than metal used in surgical instruments is: *Ivory*—unaffected; *Silk* (experiments by Professor Speakman, University of Leeds)—not significantly affected; *Natural rubber*—elongation 10.5 percent after six hours' boiling—not significant in practice, but synthetic rubbers, which would be totally unaffected, could be substituted if desired; *Insulating varnish*—unaffected; *Glass*—refluxed for 70 hours—insignificant losses; *Aluminum handles*, unless dipped initially in neat AC.10, are slightly attacked by the alkali.

The AC.10 method permits sterilization by boiling, without corrosion, of all instruments for ophthalmic surgery rapidly and simultaneously in existing sterilizers.

As knives can be boiled for five minutes or more in 2-percent $\text{Na}_2\text{CO}_3 \cdot 10 \text{H}_2\text{O}$ without harm by the AC.10 technique, one of us (K. I. J.) determined whether protection of the cataract-knife blade by immersion in AC.10 and subsequent boiling in an emulsion of AC.10 in sodium-carbonate solution could be used

to replace the customary boiling in a 2-percent solution of sodium carbonate (decahydrate), without invalidating sterilization.

Technique. The blades were sterilized by flaming and each was dipped into a dense suspension of one of the following organisms in broth:

Staphylococcus albus (coagulase negative)

Staphylococcus aureus (coagulase positive)

Bact. coli

Streptococcus pyogenes (from a septicemia)

Pneumococcus type I

Bacillus subtilis (with spores)

After drying, the viability of the organisms on each blade was tested by making a small stab culture in an agar plate, or heated blood-agar plate for the streptococcus and pneumococcus, using only the extreme tip of the blade. Only the pneumococcus failed to give growth in most experiments (see first line of the table).

Each blade was then dipped into (1) cold, sterile AC.10 for 15 seconds, and (2) a 2-percent v/v emulsion of AC.10 in a 2-percent w/v solution of sodium carbonate (decahydrate) in distilled water, at boiling point, for 5 minutes, using a separate tube for each blade and for each reagent. Stab cultures were then made in duplicate with each knife, using the whole length of the blade. In every case, the final stab cultures were sterile after incubation at 37°C. for 18 hours (see the second line of the table).

To test for bactericidal action of the AC.10 and its emulsion, the experiment was repeated, using tubes of emulsion at room temperature (see the third and fourth lines of the table). On *Staphylococcus albus* and *aureus* and on *B. subtilis*, the AC.10 and its cold emulsion had no effect, abundant growth being obtained

in each final stab culture. *Bact. coli* gave irregular results, no growth being obtained in several experiments, due apparently to the action of the sodium carbonate itself. The streptococcus was killed in all cases at room temperature, whereas the pneumococcus rarely survived drying on the blade.

hibited on the surface of heated blood agar.

CONCLUSION. Protection of inoculated cataract knives with AC.10 and incorporation of AC.10 as a 2-percent emulsion in the 2-percent solution of sodium carbonate (decahydrate) in which such knives are boiled, does not interfere with sterilization, which is effected within 5

THE STERILIZATION OF CATARACT KNIVES IN THE PRESENCE OF AC.10.

	Stab culture	Nutrient Agar				Heated Blood Agar	
		Staph. albus	Staph. aureus	Bact. coli	B. subtilis with spores	Str. pyogenes	Pneumococcus
Sterilizing experiment: Emulsion at boiling point	Initial	+	+	+	+	+	0
	Final	0	0	0	0	0	0
Control experiment: Cold emulsion	Initial	+	+	+	+	+	0
	Final	+	+	+	+	0	0

+ = Growth.
0 = No growth.

Two further lines of investigation were followed, being suggested by the aforementioned results, which are here only briefly reported:

(1) The rate of destruction of *B. subtilis* spores in the emulsion of AC.10 in sodium-carbonate solution at its boiling point and in the separate constituents of the emulsion.

It was found that the spores of *B. subtilis*, a proportion of which will retain their vitality after boiling in water for 10 minutes, are rapidly destroyed in the emulsion at boiling point, 5 minutes being adequate to attain sterility. The presence of sodium carbonate was essential to the destructive effect of the emulsion.

(2) The bactericidal action of AC.10 emulsions for *Str. pyogenes* and the pneumococcus. AC.10 as a 2-percent emulsion in distilled water is markedly bactericidal for the pneumococcus; less so for *Str. pyogenes*, and has no comparable action on *Staph. albus* or *aureus*, *Bact. coli* or *B. subtilis*. Bactericidal action is in-

minutes for all organisms tested.

BIOLOGIC REACTIONS OF AC.10. Professor Passey (Department of Experimental Pathology and Cancer Research, University of Leeds) arranged facilities for intensive instillation in the conjunctival sacs of rabbits for two weeks with a negative result, and added that the dilution and time factors would invalidate any remote effect from the irritant substances occasionally present in petroleum.

In 120 eye operations, including 25 cataracts, which have been carried out successfully by this method since November, 1944, there has been no reaction.

STERILIZER DESIGN. If the surgeon trying the method is disconcerted by the slight greasiness of the instruments, a separate compartment can be made in the sterilizer for AC.10 emulsion (for knives and keratomes only, in a small tray). One rub with sterile gauze brings all except molecular film off the handles, and a touch removes any excess from the blade. If the slight greasiness causes no incon-

venience, or if there is time to rub each instrument separately, all can be sterilized together in existing sterilizers. Trays with a locking bar to hold instruments in order of use, and to serve simultaneously as lifting fulcrum, are made to the design of one of us (J. F.) for both methods by Thackrays of Leeds.

AN ARTERY IN THE CANAL OF SCHLEMM

MR. EUGENE WOLFF in describing this vessel said that it lay toward the posterior (the scleral-spur end) of the canal of Schlemm.

It has a well-developed muscularis and is, therefore, an artery. It is some 60 μ in diameter and contains red cells, whereas the canal on either side of it appears empty.

The artery is surrounded by loose connective tissue which is not sclera, for its texture and staining properties are different. It stains, in fact, like that tissue which is normally found in varying quantity between the endothelium of the canal of Schlemm and the sclera.

Superficially, this tissue meets the sclera, while on its deep surface it is continuous with the spongework of the ligamentum pectinatum.

The artery, therefore, lies in the canal and not in a partition between two portions of it. This may or may not be of purely histologic interest. Followed in serial sections, the artery is found to come from the anterior ciliary arteries. It is part of a circular vessel which runs parallel with the canal.

Maggiore, in his classical article, was the first to describe arteries as occurring normally in the immediate neighborhood of the canal of Schlemm. This has been confirmed by Theobald and others. Maggiore figures a circular artery running close to, and parallel with, the canal, and some of his illustrations appear to show

an artery actually in the canal.

The finding of an artery in the canal of Schlemm, therefore, should cause no surprise. It might quite well be that, if the huge work of cutting complete serial sections were undertaken, an artery might be found in some portion of the canal in every globe. In any case, it is part of the circular artery figured by Maggiore.

As to the significance of an arterial system of vessels in close relation to the canal of Schlemm, it seems probable that they may exist, since the sclera itself requires very little nourishment, for supplying those afferents to the canal to which Friedenwald has lately drawn attention.

The artery here described was found during the routine examination of sections of an eye removed for malignant melanoma of the iris, which, however, had nothing to do with its presence.

THE EFFECT OF ALUMINUM AND ITS ALLOYS ON HUMAN AND RABBIT EYES. A SYNOPSIS

MR. L. H. SAVIN said that his interest in the subject was aroused by seeing, among the Dunkirk wounded, a number of eyes in which aluminum-alloy fragments were embedded. He followed for three years the case of a young sergeant in whose only eye a fragment of aluminum zinc lay in the retina. The metal was at first bright and silvery. Later, it became coated with a white cover of hydroxide. The fragment shifted twice, each time leaving a retinal "imprint," before eventually disintegrating into white powder. A second case behaved similarly.

Thirty-one implantations of aluminum and alloy fragments were made into the anterior chambers of rabbits by a standardized technique; and 10 vitreous-chamber implantations. There was no clinical difference in the behavior of pure alumi-

num and various alloys tried in doses varying from 0.3 mg. to 20.0 mg.

The fragments were observed to become coated with white powder, with a yellowish exudate, with fibrin, or in late cases with jelly. A late change often seen was powdering and fragmentation of the metallic fragment. In six cases, the fragment was completely absorbed.

Common local changes were necrotic "imprints" left by the metal; of these, 6 imprints were corneal, 12 on the iris (9 gray, 2 white, 1 necrotic), 2 in the lens, 4 in the fundus.

General effects on the eye included lens opacities in 28 eyes. Types of opacity included striae in 13 cases, dots or vacuoles in 10, irregular opacities in 10, and 4 cases with polychromatic luster. The situation might vary: 5 anterior-capsule instances; 6 anterior-cortical, 2 capsular imprints, 3 complete cataracts, 4 posterior-cortical.

Quiet inflammatory changes in the uveal tract were frequent. There were: 10 posterior synechiae, 2 cases of iris bombé, and 14 cases of iris atrophy.

Other changes included pathologic fundus pigmentation in 23 instances, 6 cases of localized choroiditis, 3 of retinitis proliferans. In order to obtain standardization of fundi initially, a special chin-chilla-rex cross was bred. Partial coloboma of the choroid was not uncommon in rabbits.

Pathologic vascularization occurred often; there were not enough controls to decide whether the reaction was specific for aluminum.

Among other oddities were noted 2 cases of bullous keratitis, 1 staphylomatous eye (false buphthalmos), 2 cases of zonular keratitis, 1 interstitial keratitis, 1 deep keratitis, 2 pigmented corneas, 1 pigmented limbus, 2 folds in Descemet's membrane. These were interesting but statistically unimportant.

Histologic changes were mostly what would be expected from the clinical appearances. Attempts were being made to trace the aluminum through the tissues by special dyes.

Altogether it was definite that aluminum was by no means inert as supposed by some previous observers. In these cases, the experimental fragments had been probably left insufficiently long.

DACRYOCYSTORRHINOSTOMY: A SIMPLIFIED METHOD

MR. T. M. TYRRELL presented this subject and illustrated his talk by a moving-picture film. He said that the main points of the operation were: (1) The incision was a long one to give a good exposure. (2) The operator attempted to remove the lacrimal bone in one piece by three blows with the hammer and chisel. (3) No attempt was made, as in other operations of this nature, to preserve the nasal mucosa, as it was not used in this operation to make the anastomosis. (4) The patency of the anastomosis was assured by repeated syringing over a long period.

Mr. Tyrrell did not wish to advocate this as a superior operation to those already practiced, but wished to point out that it had the great advantage of speed, as it could be done easily in 10 minutes, provided that one used some form of sucker to control the bleeding.

The anesthesia was 5-percent novocaine with adrenalin for the skin and tissues down to and including the periosteum. For the nasal mucosa, the nose was first sprayed with 20-percent cocaine and then a pledget of wool on an orange stick was pushed up the nose armed with cocaine and adrenalin paste.

DR. A. RAY IRVINE, *chairman*

SYMPOSIUM ON CONGENITAL ANOMALIES OF THE EYE FOLLOWING RUBELLA

Dr. A. Ray Irvine opened the symposium by stating that, due to recent articles in the literature, a new interest had arisen concerning congenital cataracts. He stated that he and his fellow staff members of the Children's Hospital were conducting the symposium for the purpose of advancing their information on the subject.

Dr. John P. Lordan stated that he began to realize the existence of this syndrome 18 months ago. He said that since Dr. Albaugh had recently written a paper on this subject, perhaps it would be better for him to summarize the problem before the discussion began.

Dr. C. H. Albaugh summarized the material available at the Children's Hospital.

Dr. A. Ray Irvine opened the discussion by bringing out the differences in type of cataract. He had seen approximately six to date. Two of these were also associated with buphthalmos and all of them with congenital heart disease.

Dr. Henry of Pasadena brought up the subject of abuse of the theory that abortion should be induced in young mothers who are known to have had rubella in the first few weeks of pregnancy. He felt that many might present themselves and state that they had had rubella merely in order to have their pregnancy terminated.

Dr. John P. Lordan suggested that the Section should bring up material and summarize it; then send such material to the Governor of the State of California, with the view to specific legislation.

Dr. A. Ray Irvine said that he agreed

it might be advisable, but that the consensus seemed to be that we should know more about the disease syndrome.

Dr. Sidney Brownsberger discussed the use of convalescent serum. He felt that, in as much as it works in measles, it might well be of value here.

Dr. Albaugh agreed with Dr. Brownsberger that it might be advisable, but he felt that in a great many instances women do not realize they are pregnant until it is too late to give such serum; moreover, specific convalescent serum would be available only in large centers where there are communicable-disease hospital units.

Dr. Jeancon said that in her experience only 50 percent of women who had had rubella in the early stages of pregnancy gave birth to babies with congenital cataract.

Dr. Walter Roberts of Los Angeles asked Dr. Jeancon about the available statistics from Australia, which indicate that 100 percent of the women who have rubella in the first two months will give birth to babies with congenital cataracts and other congenital anomalies. He stated, however, that he had seen one case in which a woman was proved to have had rubella, but the infant was born normal.

Dr. Irvine brought up the question as to why these babies get cataracts.

Dr. Alfred Robbins, in turn, asked whether this disease really is rubella. He discussed the embryology of the lens and showed slides indicating the various stages of its development during the first few week of embryonic life. He considered that any disease in early pregnancy may cause such congenital anomalies in the eye, and urged caution in making any resolutions officially, saying that there is plenty of time to observe this syndrome to determine what its true nature really is.

Dr. Dennis Smith of Long Beach stated that he believed this to be another manifestation of an ectodermal disease.

Dr. Alexander Ray Irvine, Jr., asked why other diseases might not as well cause congenital cataracts. He discussed the relationship between rubella and fibroplasia, and stated that this also fitted in with the congenital heart lesions.

Dr. Albaugh asked why some of the patients do not have all the manifestations; that is, all the congenital anomalies. He wondered why some had heart disease, some had congenital cataracts, and some might have both, while still others might be deaf mutes.

Dr. John P. Lordan, in reply to the question, what are the differential points concerning the lens in the absence of a history of rubella in such types of cataract, said that a nuclear cataract with a typical complication, such as heart disease and deaf-mutism, is the answer.

Dr. Robbins stated that he was not so sure of the diagnosis; that he had seen four such cases, none with identical pathologic changes in the lens.

Dr. A. Ray Irvine reported a case from his practice in which there was a definite cortical cataract which was similar to a traumatic one.

Dr. Dennis Smith related the case of one of his patients who had been a premature infant and whose mother had had rubella in the early weeks of pregnancy. There were typical signs, such as cortical opacity and cloudiness of the cornea with congenital heart disease. He stated that at first the anterior chambers were not shallow; that the corneal opacity cleared. Later the whole lens became opaque and the cornea became edematous. Congenital glaucoma followed several weeks later.

Dr. John P. Lordan discussed his ideas of the therapy of such cases. He stated that, in the first place, these infants were supposed to be more atropine sensitive than are normal children. He felt that this was not the case—it was simply over-dosage and not a specific sensitivity.

Most of these babies, he said, are underdeveloped and will not tolerate so much atropine as the normal child. On the whole, he thought that little could be gained by very early surgery because the pupil could not be dilated well.

Dr. Robert A. Norene stated that he had never had any difficulty with dilating the pupils in these patients, but that he had not used atropine. He found that neosynephrin was efficacious. He cautioned that it should be used carefully, in as much as the babies who had associated congenital heart disease might react excessively to a cardiac stimulant.

Dr. Warren Wilson stated that the diagnosis of rubella could be very easily overlooked. He discussed an epidemic he had seen, in which the cases were diagnosed as sore throat for some time before it was realized that it was an epidemic of true rubella. He said many of these patients go first to the Ear, Nose and Throat Clinic and are missed as rubella.

Dr. Welch of Glendale suggested that everyone be inoculated with both measles and German measles in childhood.

Dr. Dennis Smith wished to know about the optimum time for surgical intervention.

Dr. Mel Trainor stated that he always operated in these cases within the first year, and, if a needling was not done, he performed an optical iridectomy in order to give stimulation for development of the macula.

It was the consensus of the members of the staff that early operation is indicated in order to develop the macula properly.

Dr. Alfred Robbins stated that he operates as soon as possible. He also reported that the pupil dilates well with neosynephrin. He uses a special technique of his own in which he opens the anterior capsule of the lens and sucks out the corti-

cal and nuclear material with a special device of his own design. However, he is cautious about surgery from the standpoint of an anesthetic. He always waits until the pediatrician indicates that the child is in condition to stand general anesthesia.

Dr. John Lordan initiated a discussion of other congenital defects following rubella in early pregnancy. Among others, he had had several cases of buphthalmos. He felt that the mechanism was somewhat as follows: if the tissues around the angle are disturbed in early pregnancy by the process involved in rubella, the normal atrophy which leaves the trabecular network cannot take place, with the result that the canal of Schlemm and its mechanism are not developed. He believes that the procedure of Barkan—namely, anterior sclerotomy or goniotomy—is the indicated surgery.

Dr. A. Ray Irvine agreed with him and stated that he felt Dr. Barkan's results were 40 to 50 percent cures.

Dr. Endres stated that in his opinion it was economically impossible to send many of these cases to Dr. Barkan in San Francisco and that someone in Los Angeles should cultivate such a technique.

DR. M. B. SELIGSTEIN, *presiding*

CONGENITAL STENOSIS TREATED BY PLASTIC DACRYORHINOSTOMY

DR. RALPH O. RYCHENER reported on Larry G., aged two years, who was first seen on December 18, 1942. Congenital stenosis of both eyes, had been observed

soon after birth, but treatment was delayed until June, 1941. Two months later fluid passed through the right duct and this eye gave no further trouble. However, stenosis persisted on the left side, despite 80 probings by a local colleague. On inspection, a large mucocele was found in the left sac with no evidence of infection. A double-0 probe was passed into the canal, an imperforate lumen ruptured, and fluid then passed freely into the nose. The duct remained open for a week, but, following an acute rhinitis, obstruction developed, and it was not possible to reopen the lacrimal passage thereafter. On June 19, 1943, a plastic dacryorhinostomy was accomplished, with permanent relief of symptoms.

Dr. Ralph O. Rychener reported a second case of congenital stenosis for which dacryorhinostomy was performed. F. C., aged five years, was referred to him on February 4, 1942, by Dr. A. D. Frost of Columbus, Ohio. Congenital stenosis was noted early, but treatment was not instituted until the child was 21 months old, when probing with the giant probe, after slitting of the canaliculi, was done. Although fluid could be forced through the passage into the nose, retention mucoceles persisted, and there was a constant lacrimation and backwash of purulent material into the conjunctival cul-de-sac.

Mucoid material could be regurgitated by pressure over the lacrimal sacs, and injection of iodochloral showed by X ray that the sacs measured 3 by 6 mm. and 5 by 10 mm., respectively. Fluid could be passed through the right sac under moderate pressure.

Under ether anesthesia, plastic dacryorhinostomy was done on the right sac, on February 11, 1942, and on the left sac, February 14th. The first operation was uncomplicated, but the second involved a cavernous plexus in the lacrimal fossa, resembling a hemangioma from which

there was considerable loss of blood. It was also necessary to extenterate some accessory ethmoid cells before the nasal mucosa could be reached. Glucose—175 c.c of a 5-percent solution—was given intravenously. Postoperative convalescence was uneventful. Fluid passed freely through both sacs by the sixth postoperative day. A letter from the parents on December 18, 1943, reported that both eyes were dry and giving no further trouble.

PIGMENTARY DEGENERATION OF THE RETINA WITH CATARACTS AND DEAFNESS

DR. PHILIP MERIWETHER LEWIS presented a white woman, aged 38 years, who had noticed for two years that her vision was failing.

Examination showed corrected vision to be: O.D. 10/200 and J10; O.S. 20/100 and J8. Immature nuclear cataracts were present in both eyes, but the visual fields were badly contracted, and the projection of light faulty. On dilating the pupil, an atypical form of pigmentary degeneration was found. The patient was

also quite deaf and had been all of her life. She has two normal children, a boy of 11 and a girl of 9 years. During a pregnancy, two years before, she thought that her vision became much worse. This child lived only a few months. The cause of death was unknown. The patient's general condition and blood were normal.

Three other members of her family were examined. One brother and one sister, aged 45 and 43 years, respectively, had pigmentary degeneration of both eyes and also deafness. One sister, aged 49 years, had normal eyes and good hearing. One brother, aged 41 years, lived too far away to be examined, but was reputedly normal. The parents had been killed simultaneously by accident in their middle fifties. Both had had good sight and hearing; they were not related.

The question in this case was whether or not to remove the cataracts. In view of the bad prognosis and the likelihood of complete blindness eventually, it was thought that operation was contraindicated as long as the patient had any useful vision.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Miss Emma S. Buss, 121 Woodbine Avenue, Wilmette, Illinois. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Abnapp Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

NATIONALIZED OPHTHALMOLOGY IN BRITAIN

The Labor Government in Britain has been in power a little over nine months and is now in the throes of giving birth to the National Health Service Bill; and, although it is not yet law, it is already clear what the general outline of the new socialized medicine will be. For better or for worse, the whole aspect of British medicine is to change. No one who knows it and its shortcomings, particularly in the rural areas, will deny that many

changes would be desirable. It may be of interest to American readers to know what is contemplated, for—who knows?—a similar fate may some day descend upon them.

From the point of view of the people, all medical facilities, both hospital services and personal medical attention, are to be offered "free" to any citizen who wishes to avail himself of them—that is, free to the sick person at the time, and paid for as a national charge, partly from a universally levied weekly insurance and

partly from general treasury funds. Incidentally, the insurance also provides birth allowance, children's allowance, sickness allowance, unemployment allowance, old-age pension, and provision for funeral expenses.

In general terms, from the administrative point of view, medicine is considered in two parts: the general-practitioner service and the hospital and specialist service; into the latter comes ophthalmology. All the hospitals of the country are to be taken over by the State, and the country is to be divided into some 16 or 20 regions, each of which is centered upon a university teaching school. Each of these regions is to be administered by a regional hospital board appointed by the Minister of Health, and their function is to coördinate and administer the specialist services in its area and lay down general lines of policy, the day-to-day administration of individual hospitals or groups of hospitals being delegated to local committees appointed by them. It is proposed to have a full and regionally planned hospital and specialist service available throughout the entire country: each hospital, whether rural or urban, whether previously wealthy or poor, will have comparable material facilities and comparable financial resources. Although they must conform to the general plan of hospital services designed by the regional boards, the teaching hospitals are to be allowed to retain a certain degree of individuality, since they are to be administered by separate boards of governors and may individually retain their endowment funds.

Ophthalmologists, as other specialists participating in the National Service, will thus be appointed by and in the employment of the regional boards (or the boards of governors of teaching hospitals). The whole of the practice of ophthalmology is to be institutionalized.

Consulting and operating work will take place in the hospitals. The routine eye-testing and the provision of spectacles must, for obvious reasons, be more fully disseminated among the population, and these are therefore to take place not only in the hospitals but also in a large number of satellite clinics administered by them, functioning on a whole-time or part-time basis, depending on the needs of the locality. These clinics are to be staffed by an ophthalmic specialist, junior ophthalmologists under him (in the larger clinics), and, also under him, optometrists (sight-testing opticians) will do the bulk of the refractions. Spectacles will be obtainable ("free") at the clinic or at the shops of dispensing opticians who contract in to the service, but if they are broken or lost as the result of carelessness or if the patient chooses to be supplied with more expensive spectacles than those issued by the State, he will be expected to meet the additional cost involved. Until the clinic system becomes materially possible (and this in many districts will take some considerable time owing to lack of suitable buildings), as an interim measure the present system will virtually be carried on—patients will have a free choice of going without fee for refraction examination either to an ophthalmologist (at a clinic or his office) or an optometrist (at his shop).

A feature of the scheme of peculiar interest is the new relationship contemplated between ophthalmologists and opticians. It is quite obvious that in no measurable time could all the refraction work be done by medical men: no ophthalmologist in Britain today is idle, and yet some 75 percent of the refractions in the country are done by optometrists, and a universally "free" service will undoubtedly increase the demand very materially. Furthermore, it would not be economic that 10 years of training (the time which

will probably be demanded for the total training of a specialist) should be required for the routine examination of the optical state of all eyes, the vast majority of which are free from pathologic change. The ultimate arrangement, whereby all optical examinations are conducted under medical control, appears to be the most adequate arrangement possible, the junior ophthalmologist, the optometrist, and the orthoptist being supervised by the surgeon in charge of the clinic. Initially, in order to avoid hardship, it is the government's intention to employ in this way all adequately qualified optometrists on a rota system if necessary; the suggestion is that new entrants to the profession, however, will be required to become either whole-time "refractionists" or whole-time "dispensing opticians" so far as the State service is concerned. In the past, there has probably been as little love lost between ophthalmologists and opticians in Britain as in America, but it may be that when both parties fall into an allotted role the animosities of the past will be lost in coöperation in the future.

Where will all these changes lead British medicine? That is a question which today is very difficult to answer, and the reply will almost certainly vary with the political leanings of the individual. It may be argued that it is wrong that the care of the poor when they are sick should depend on the charity of the rich, that this should fall as a duty upon the community as a whole, and that the voluntary system allows many to escape their social obligations. It is true that hospital services and specialist facilities should be organized over wide natural areas and not confined to the capricious boundaries of local government or conditioned by the attractions of wealth or social amenities. It is certainly true that in the poor community, or the wealthy, an equally complete and efficient hospital

service should be readily available for all. Moreover, as wages and prices rise and medicine becomes increasingly loaded with complicated equipment, the voluntary hospital must look forward with anxiety to a future wherein gifts are limited by unprecedented taxation and legacies are rendered almost impossible by death duties of confiscatory dimensions.

There are certainly many arguments which are difficult to confute in favor of such a national service, and many good points in the proposals outlined in the bill. On the other hand, there is a deficit account, and those who have been brought up in the spirit of a voluntary hospital cannot but have many misgivings. Will the loss of the local interest and local responsibility which gave individuality and vitality to the voluntary hospital be compensated by increased efficiency in a huge bureaucratic mechanism directed from afar by government servants, with the inevitable lack of elasticity which this must entail even in the most gently guided State scheme? Is the wisdom, the capacity, or the humanity of the State so great as to outweigh personal intimacy and interest and to justify a State monopoly of hospitals? There may be a gain in the technical machinery and financial resources available to medicine, but, unless the treasury changes the habits of centuries, will this carry with it individual frustration and submergence in administrative regulations? Time will show. Those of us who have served in the army may be able to suggest an answer. The administrative success of the scheme will depend in very large measure on the amount of decentralization allowed, on the wisdom of the regional boards, and on the degree of local financial freedom permitted within the limits of a reasonable budget.

So far as the ophthalmologist is concerned he will, to the extent to which he

participates in the service; receive the security of a regular pay-packet from the beginning of his professional career and a pension at the end in exchange for the adventures of private practice with its risks and possibilities; he will be deprived of many opportunities of doing much without material reward, but will incidentally be less his own master than formerly. So far as medicine (and ophthalmology) is concerned the new plan will be good in the final assessment only in so far as it can continue to attract brilliant young men and reward them sufficiently, and only if they have ample opportunity for initiative and the full expression of their personalities; there are few glittering personalities without glittering rewards, and medicine will be in competition with other comparable professions which as yet are not nationalized and may provide more individual scope.

It is anticipated that the present bill will become law in the early fall and that the national service will start to function in the beginning of January, 1948. It will then be necessary for each practitioner to decide whether or not he will take part in the service, either whole time or part time; but it is difficult for the consultant not to be at least a part-time participant; since all hospital facilities will belong to the State. With the present relations between the public and the profession, private practice will undoubtedly continue so long as the present generation lives. Everyone pays education rates in England, yet many send their children to Eaton. But social ideas change, and with heavy social levies double payments become more difficult. Certainly the danger potentially exists of the gradual abolition of private practice and the ultimate development of a State monopoly of medicine: the avowed aim of the Labor Party is a full-time State-salaried service "when the time is ripe." With State con-

trol of all hospitals, such a development would be easy, and very wide powers are to be vested in the Minister of Health—whoever he may happen for political reasons to be. This, accompanied as it would be by the greatest black market of all time, would, I think, be a tragedy for British medicine. As a whole, doctors today have the interests of medicine at heart; but whether the type of man who will be attracted to a State service in the future will be equally enthusiastic is another matter. On this will depend in part the ultimate success of this social experiment. In part it will also depend, unfortunately, on factors quite outside the control of medicine which hitherto have not always been uniformly dependable—on the wisdom of politicians and the understanding of civil servants.

Sir Stewart Duke-Elder.

OPHTHALMOLOGY SCORES AGAIN

It is a matter of common knowledge that ophthalmologists are modest, retiring fellows, and loath to praise themselves. This commendable trait can be overdone. Thus, no one has seen fit to applaud the course just launched by the Ophthalmological Study Council, so it falls to us to commend this last achievement of our specialty.

We are not alone in the emergency that instigated this project. All the medical specialties were faced with a 5-years' supply of candidates for special training disgorged by the Armed Forces. In ophthalmology there were opportunities to accommodate less than the normal quota of men for a single year. Their preparation falls roughly into three different categories: One group had had no special training, but was headed toward ophthalmology when taken into service; another had started special study, but was not

established in practice; a third was in practice before the war but wished for refresher courses. Most men in all groups were either contemplating the examinations for the certificate of the American Board of Ophthalmology, or had already tried them and been found wanting in some or all subjects. Consequently, they were desperately bombarding the Board with impatient letters inquiring into two problems. These were, first, how much credit the Board would allow for Army and Navy service. The reply to this was wholly unsatisfactory. The Board gave credit only for ophthalmologic experience so obtained. Because much of the service with the Armed Forces entailed no such experience, this led immediately to the second question, which was how the Board justified its position in establishing standards which could not possibly be attained by the great majority of the candidates under existing conditions.

While the Board was adamant as to the qualifications to be recognized as indicating competence in ophthalmology, they had to admit that there was some justice in this complaint. The Board itself does not intrude directly into the teaching field, beyond making every reasonable effort to stimulate existing teaching institutions. In this emergency the response was prompt and effective. The larger universities and hospitals readily agreed to increase their students and residents, often doubling and more than doubling the numbers. Many leaders in practice were willing to act as preceptors, especially for young men who had had residencies and basic courses. But after all these opportunities had been utilized, the Board was still swamped by applications of men who could obtain no places, most of them veterans who had made considerable sacrifice for the general good.

This was the situation when Prof. Ida

Mann, who was guest of the American Ophthalmological Society at its Hot Springs session, in November, 1945, described the training course in use in England for men in service. It was a sort of mass production basic course. Pathology, to illustrate, was not administered to a few lucky students with microscopes, but was taught to large classes by throwing sections on the screen with a lantern.

This seemed to offer the logical solution to the problem, but, on proposing it, there were more reasons for delay than obstructed the invasion of France during the war. The very fact that the hospitals and schools had generously overextended themselves in this cause, prevented them from undertaking anything additional, especially such a novel experiment as this.

So at the end of the year the secretary of the Board was unexpectedly invited to a conference in Boston with Dr. Walter B. Lancaster and Dr. Theodore L. Terry. It was a carefully planned meeting, evidently not so impromptu as it seemed, and, somewhat to the surprise of all, it reached a decision to offer a course in the basic subjects of ophthalmology in Boston, during April and May of 1946. It was believed that if the course were to be of use it must proceed at once, and four months seemed the shortest time in which arrangements could be made. In view of the foreseen and unanticipated obstacles that were encountered, this interval was decidedly brief.

Now is a good time to answer the inquiries from colleagues contemplating a similar course, as well as from teachers in other specialties. The detail was enormous. Either because of it, or coincidentally, Doctor Terry fell by the wayside and was sent to the hospital, and then away to convalesce. Not, however, until he had made his contribution to the organizing. The work then fell upon Doctor Lan-

caster. Possibly the launching of the course on time was due to having a one-man committee able to make instant decisions. The result was that Doctor Lancaster was also laid up, just as the course began. Only the versatility of a few secretaries prevented a traffic jam on registration day.

Perhaps a brief review of the arrangements required will reduce the casualties among future organizers. Without attempting a blow-by-blow report, one may say that these are the main headaches. First, where would such a course, having no hospital or medical-school backing, be given. At this time, the venture did not even have the renowned shoestring, which has so often brought success. Fortunately, the hall of the Boston Medical Library was available, and the managers made no embarrassing inquiries about the solvency of the course. Then, many of the local teachers, who would normally have been asked to teach, were already under contract to the extra session of the 4-months' basic course which the Harvard Graduate School of Medicine had organized in response to the pleas of the Board. So faculty must be in considerable part imported. This seemed at first likely to be as difficult as getting nylon stockings, but it turned out to be the least of our troubles. No one refused. The finances required much more maneuvering. The obvious source of support was the Veterans' Administration appropriation under the G.I. Bill of Rights. The authorities, however, were canny, and required unshakable proof that the G.I. was not going to be swindled by either shysters or visionaries. If funds were to be authorized, incorporation and approval of the proper authorities of the Commonwealth of Massachusetts must first be forthcoming. So an imposing group of incorporators had to be enlisted. This offered no particular difficulty, but took much valuable time. Fur-

ther confidence was built up by inviting an advisory board of outstanding teachers.

An unexpected problem arose in the housing and nourishment of a large group like this. At that time, Boston doctors were unable to obtain rooms for single patients who wished to consult them. The hotel association could not promise any accommodations for such an indefinite number of men, many with families. They did, nevertheless, find a summer hotel some 20 miles out, which was willing to open a couple of months early, and offered reasonable rates. This method required a bus service to get the students to and from classes, and their wives to and from stores.

In the meantime a curriculum had to be determined, hours assigned, and teachers fitted to the hours, or hours to the teachers. With many of the most illustrious faculty as far away as Baltimore and Chicago, this would have made a complicated job even for a veteran train dispatcher. It was decided to hold sessions morning, afternoon, and evening. While this seems to exceed union hours, in practice it was not too arduous. Lectures were limited to five or six a day. Considerable rest periods, quizzes, and examinations were interspersed. Usually the week ended Saturday noon.

One problem common to all such courses is as unsolvable as uniting the United Nations. That is adapting such instruction perfectly to the needs of such diverse groups, one of which had never had any ophthalmology; another with considerable knowledge of the fundamentals; and a third with a varying amount of actual practice. To complicate this situation still further, textbooks were entirely unavailable, and would not be issued until sometime in the summer. Thus more textbook material would have to be repeated in the lectures than would usually

have been the case. This necessitated some method of reproducing the lectures of those instructors who spoke without notes. Stenotypy, which has been used in some refresher courses, was too expensive. Ediphone equipment was therefore purchased, and hooked up with the broadcasting apparatus in the hall. This necessitated obtaining secretaries to transcribe the records, no mean task with the shortage.

The result of this hastily organized project was better than could have been supposed. That some "bugs" would creep into such a novel scheme is inevitable. They were not always the ones that were foreseen. New England weather had to live up to its reputation. An untimely blizzard hit the area in April, to extend its welcome. Consequently the men on reaching their hotel on registration day found their families almost rigid with cold in an inadequately heated summer hotel. Many at once sought quarters in Boston though not always what they would have chosen. Then, in response to questionnaires, it seems that more concentration in the daytime, and no lectures in the evening would have been more popular. As would be expected, beginners felt that "too much was taken for granted" and experienced men called some elementary work "sophomoric." Now that textbooks are again available, this last objection could be avoided in a later course.

At \$200 for the course, the cost was about \$25 a week, which is probably too little. It gave the organization, with between 75 and 100 students, an income of over \$18,000, which just about covered expenses, allowing a modest recompense to the lecturers.

The general attitude was favorable. In fact the demand for a repetition is such that a similar course is projected in Florida during November and December. This does not necessarily mean that it will be-

come a permanent institution. It was planned as an emergency measure to meet the immediate need, in which, as usual, ophthalmology has pioneered.

S. Judd Beach.

IRIDENCELEISIS AND TENON'S CAPSULE

Almost forty years ago Holth of Christiania (now Oslo) published what must be regarded as one of the classics of ophthalmic literature, under the title of "Iridenceleisis antiglaucomatosa" (*Annales d'Oculistique*, 1907, volume 137, page 345; originally presented in 1906 to the Medical Society of Christiania; also in condensed form to the French Ophthalmological Society and to the German Ophthalmological Society in Heidelberg). Holth's paper is a model of clear thinking and patient observation.

Except as to iridectomy, proposed by Graefe for the relief of glaucoma fifty years earlier, previous operations against glaucoma had aimed to establish a new channel of drainage of aqueous humor by excision of sclera beneath a conjunctival flap. Holth's operation, generally speaking, excises no tissue; and it depends for a successful result upon the formation of a new drainage channel associated with incarceration of the pigmented iris between the lips of the scleral wound.

Two or three years before publication of Holth's paper, the study of glaucoma had taken a great step forward with the introduction of the successful tonometer of Schiötz, another Christiania leader. Holth had tested with the tonometer a series of glaucomatous eyes which had been subjected to iridectomy. Except within the first few weeks after the operation, he found the intraocular pressure generally above normal. Strangely enough, and in spite of the dread of iris

prolapse as a dangerous complication following any intraocular operation, Holth learned that the iridectomized eyes which had been relieved of their hypertension were usually eyes in which the technique of the operation had been regarded as defective in that iris tissue had been left in the scleral wound.

Holth therefore made an intentional experiment upon the two equally hypertensive eyes of the same patient (54 mm. Schiötz), doing an ordinary iridectomy upon the blind eye and on the other eye an iridectomy with incarceration of the iris beneath the conjunctival flap. In the former the tension fell to 43 mm., in the latter to 24 mm. Comparison of other cases of accidental incarceration with cases in which the iridectomy had been classically performed supported the conclusion that the subconjunctival incarceration was beneficial instead of harmful. Holth therefore proceeded in a number of cases to perform iridectomy with intentional incarceration, and his original article reported a goodly series of excellent results.

The technique of iridencleisis has undergone various modifications at the hands of different surgeons. Holth himself preferred a keratome incision, picking up an 8- or 10-mm. conjunctival flap, pushing the keratome along the sclera to within a bare millimeter of the limbus, and then drawing the iris sphincter into the scleral wound and making a meridional cut to one side of the forceps. Others have made the incision with the Graefe knife, although Holth had tried this method and did not favor it. Some surgeons have worked through a small conjunctival opening made with a Graefe knife. Occasionally, operators have dissected a conjunctival flap from the limbus peripherally (Van Lint flap). Some have performed the usual type of iridectomy, but leaving iris tissue in each angle

of the scleral wound. Others have combined iris incarceration with excision of sclera as recommended by Lagrange.

Reese (*Archives of Ophthalmology*, 1945, volume 34, page 360) has lately urged the same type of keratome approach as originally advised by Holth; succeeded by the making of traction on the pupillary margin at two points (by operator and assistant synchronously) until a dialysis is produced between the two points of traction; and lastly division of the iris at right angles to the pupillary margin, followed by incarceration of each pillar of the iris into an angle of the wound.

Approval or disapproval of the iridencleisis operation by the individual operator seems to have varied greatly according to his previous preference for other operations (the Lagrange or the Elliot especially), or according to the custom of surgeons in the same part of the world. No doubt an important influence has come from initial experience in performance of the operation, especially such experience as might depend upon misconception or preconception regarding technique of anesthesia or of the operation itself.

Downright opposition to the operation has been manifested by some surgeons. Torres Estrada (Mexico), for example, speaks very strongly against every fistulizing operation, and practically always performs a very extensive cyclodialysis to which he has applied the title "hemicyclodialysis" (*Boletín del Hospital Oftalmológico de Nuestra Señora de la Luz*, 1946, January-April, page 121). A few eye surgeons have had the misfortune to see one or two cases of sympathetic ophthalmia following filtration operations, including iridencleisis.

It maybe that, in discussing the technique of iridencleisis as well as the occasional failures following this operation,

we have paid too little attention to the anatomic and physiologic relations of Tenon's capsule. In describing the operation, reference is often rather loosely made to dissection through subconjunctival tissue down to the sclera in the vicinity of the limbus. Holth himself makes no direct statement in this regard. His insistence on use of the keratome rather than scissors in executing the preliminary incision may have a bearing on the subject, especially when considered in relation to his description of a keratome incision which penetrates the conjunctiva 8 or 10 mm. from the corneal margin, and then drags the conjunctival fold along the sclera to enter the eye a scant 1 mm. above the limbus.

Peters's chapter on diseases of the orbit in Axenfeld's *Lehrbuch* (seventh edition) regards the space between Tenon's capsule and the sclera as a lymph space which continues into the supravaginal lymph space of the optic nerve and is also connected with the suprachoroidal space of the eyeball. Some doubt has been cast upon the existence of such anatomic continuity.

In dissecting back a conjunctival flap for cataract operation, it is a matter of common note that the subconjunctival tissue (in Tenon's capsule) of this region varies greatly, being sometimes well defined as a special layer and sometimes less definite. But usually, after incising the conjunctiva, it is possible with care to pick up a delicate but distinct layer of fibrous tissue which may then be incised as a unit and so separated from the sclera as far as the limbus.

Meller, disapproving of iridencleisis on general principle, repeatedly avoided mentioning it in his "Ophthalmic surgery." Sweet's third American edition of the same work (from Meller's second edition) gives an account of the iridencleisis operation but makes no mention of

Tenon's capsule in this connection. The same is true of Spaeth's "Ophthalmic surgery."

Many surgeons have approached consideration of the iridencleisis operation with a definite prejudice against it, and have never been converted from this prejudice. The present writer's experience with the operation (which he first used in December, 1928) has usually been gratifying, and he is disposed to believe that some failures have been, at least in part, due to insufficient care in separation of Tenon's capsule as an anatomic unit.

Holth's very definite success in applying this procedure to a number of cases of absolute glaucoma, with tension as high as between 60 and 70 mm. Schiötz (in spite of miotics) and also as a second operation after failure or incomplete success of iridectomy, has been shared by other operators. Use of iridencleisis after an acute exacerbation of chronic glaucoma should probably be resorted to only after beneficial reduction of tension by paracentesis.

W. H. Crisp.

BOOK NOTICE

CLINICAL OPHTHALMOSCOPY.

By Arthur J. Bedell, M.D., F.A.C.S., D.Sc., LL.D. 200 glass mounted Kodachrome 2 by 2 inch reproductions with a concise history and a description of each. Distributed by James A. Glenn, 76 Columbia Street, Albany, New York. Price \$100.00. 1946.

It has been a rare privilege and a great treat for the reviewer to be able to view these slides, leisurely projected as these were meant to be, where the full beauty and the remarkable stereoscopic illusion could be fully enjoyed. Each slide beautifully discloses details that minutely express the condition. Natural colors are

faithfully reproduced, enhanced by the expertly sharp focus. The series has been carefully chosen to illustrate most of the ocular-fundus conditions that are met with in ophthalmoscopy. The collection is of great value to the teacher and should be available to all students for study and review.

The collection begins logically enough with a few slides of the normal fundus and its variations. It progresses through various pathologic conditions, each of which is illustrated with two or more slides, to end with fine photographs of a "before and after" case of an intraocular foreign body.

There are many serial pictures of the same patients taken at different intervals, some over a period of several years. Thus an unusual opportunity is afforded to trace the evolution of different disease processes and to compare one phase with another. The instructive series of slides illustrating the various grades and stages of development of retinal arteriosclerosis, vascular hypertension, and diabetic retinopathy are especially noteworthy. Their value as teaching aids in explaining and understanding this difficult subject is obvious. Another example of the teaching value of interval pictures can be readily appreciated on viewing the series of macular retino-choroiditis up to the healed stages.

It is difficult to pick out the most outstanding photographs. All are good and many are worthy of exclamation. There are no failures and few disappointments. In some of the photographs the white spots, representing the reflex from the carbon arc, have been painted out. The author points out that these should not be misinterpreted as localized pigmentation, a very real danger. It is questionable whether anything has been gained by obliterating the reflex, for the remnants are always visible. However, in one case,

that of a photograph of a detached retina, the painting out of the carbon reflex has undoubtedly enhanced the effectiveness of the slide. It is curious, too, not to see pigment deposits, for example those of retinitis pigmentosa, stand out as black as they do in life. But these are exceedingly minor flaws and are not worthy of being dwelt upon.

It is unnecessary to explain to the reader who Dr. Bedell is. His fame as an ophthalmologist and photographer of the ocular fundus is world wide. Those who have not had the chance to hear him and see his pictures at the meetings for the past many years now have access to an unsurpassed collection of what are no doubt the prizes of his many years of work.

Now if some well-known ophthalmic pathologist will provide us with a similar set of Kodachrome slides that illustrate the pathology underlying each of the Bedell reproductions, the heart of the teacher will be exceedingly happy.

The Bedell Kodachrome slides are carefully mounted in glass, numbered, and distributed in two gray, metal slide boxes with handles. A good description of each slide, covering the essential points of history and condition, is printed and bound spirally between paper covers and accompanies the collection.

Derrick Vail.

CORRESPONDENCE

POSTGRADUATE INSTRUCTION IN OPHTHALMOLOGY AT HARVARD MEDICAL SCHOOL

To the Editor,
American Journal of Ophthalmology:

In the May, 1946, number of the American Journal of Ophthalmology appears an excellent editorial by Dr. Crisp entitled "A national program for training

in ophthalmology." In commenting on the postgraduate courses given at Harvard, Dr. Crisp states, "These short programs should be stimulating to young ophthalmologists whose time was badly wasted during the war, and who are eagerly looking for refresher courses. By themselves, the two Harvard courses cannot, it is obvious, create first-class ophthalmologists."

With this I agree wholeheartedly, and lest anyone might infer from the editorial that it is the intention of the Department of Ophthalmology at Harvard to create ophthalmologists by short courses, I wish to state that just the opposite is true. These two courses were given earlier than usual, and in condensed form, to help fill the tremendous demand for instruction on the part of the returning medical officers, but they were designed primarily for young doctors wishing to take didactic work as a preliminary to their residency. Selection of candidates was carefully made on the basis of previous education and future intentions, and no one (except recognized ophthalmologists) was allowed to take the clinical course without first having had the course in fundamentals.

We believe that a residency in ophthalmology is the only proper way to obtain adequate training in this field, but that a course in the basic sciences should be a prerequisite to such a residency. This basic-science course is necessary to bridge the gap between the deficiencies of undergraduate medical-school training in ophthalmology and the clinical work in the residency.

We feel sure also that the fundamentals cannot be taught by lectures, reading, and quizzes alone, as some have contended. Laboratory work is essential, but it is questionable whether this type of basic instruction can be given properly by the average clinical ophthalmologist. In most

instances it is better done by the full-time research staff attached to an ophthalmic center.

The policy of the Department of Ophthalmology of Harvard Medical School is to give two types of postgraduate instruction: (1) A basic-science course of three months' duration given by the staff of the Howe Laboratory of Ophthalmic Research to young physicians who are going to take a residency in ophthalmology. (2) Refresher courses in clinical subjects given by clinicians and open only to recognized ophthalmologists who have already had an ophthalmic residency.

Clinical Professor of Ophthalmology,
Harvard Medical School.

DISPENSING WITH BIFOCALS

Editor,
American Journal of Ophthalmology:

Apropos of Dr. Pascal's remarks on "Dispensing with bifocals" in the May, 1946, issue of the American Journal of Ophthalmology, it may be interesting to report a case which bears out the feasibility of so doing to even a greater extent, at least in selected cases.

While in Belgium, I had known and had some contact with Prof. Allvar Gullstrand, who was wearing bifocals in which each lens was adapted for two different distances for the corresponding eye; that is, the bifocals gave Dr. Gullstrand four monocular regions of clear vision with binocular fixation. This case illustrates what can be done along this line in providing two full monocular fields of vision with a pair of differently adapted single-vision lenses.

New York, New York.

ABSTRACT DEPARTMENT

EDITED BY F. HERBERT HAESSLER, M.D.

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

OCULAR MOVEMENTS

Smart, R. E. The diagnosis and treatment of ocular muscle anomalies, Canadian Med. Assoc. Jour., 1946, v. 54, April, p. 371.

The author outlines the diagnostic procedure which he considers essential in the study of the functions of the extraocular muscles. It consists of six steps; namely,

(1) Measurement of the near point of convergence. (PcB)

(2) Maddox-rod test (with screening) at 20 feet, and at 14 inches. These first two tests are used to determine whether the anomaly is one of convergence or divergence, and if it is an excess or an insufficiency.

(3) Ocular excursions in the six cardinal directions.

(4) Screen comitance test in the cardinal directions.

(5) Cover test (with prisms) at 20 feet, and at 14 inches; then, in the cardinal positions at 14 inches. These three tests enable one to determine

whether or not a heterophoria or heterotropia is concomitant; if it is not, they enable one to identify the paretic muscles involved.

(6) Accommodation is tested with Prince's rule.

In addition to these tests, vergence tests may be necessary. At times, a prolonged monocular occlusion is of value in eliciting a heterophoria.

The question of treatment of muscle anomalies is touched upon. Emphasis is placed on the need for an accurate muscle diagnosis in the proper care of the eye patient. Benjamin Milder.

5

CONJUNCTIVA

Bietti, G. B. Action of penicillin upon the inclusion bodies in trachoma. Studi Sassarese, 1945, v. 23, no. 1, pp. 3-7.

Bietti studied the effect of penicillin

on inclusion bodies from 10 cases of recent trachoma, since this seemed the best test of the activity of the antibiotic upon the virus. Collyria containing 100 to 20,000 units per cubic centimeter were instilled every two hours. One eye only of each patient was treated, and smears were made daily from both eyes. Within 24 to 48 hours the corpuscles showed marked morphologic changes, and in 48 to 72 hours the initial bodies and the inclusion bodies had disappeared. The action of penicillin was not, however, more effective than that of the sulfonamides and did not clear up the nodules more rapidly.

Eugene M. Blake.

Bietti, G., and Scalfi, L. The sensitivity to penicillin *in vitro*, of typical conjunctival bacteria. Studi Sassarese, 1945, v. 23, no. 1, pp. 3-4.

The writers isolated 51 cultures of nonliquefying *Staphylococcus albus*, 12 of liquefying *Staphylococcus albus*, 13 of *Staphylococcus aureus*, 34 of diplobacillus, 24 of *B. xerosis*, and 6 of Koch-Weeks bacilli. The organisms were grown in agar, broth, Loeffler's serum, and blood agar, to which penicillin had been added in concentrations of 0.01 to 5 Oxford units per cubic centimeter of culture medium. *Staphylococcus* was found most sensitive to the drug, with very little difference between the three types. Next in order was *B. xerosis*, then the Morax-Axenfeld diplobacillus. The Koch-Weeks bacillus was practically unaffected. The most striking result of the study was the fact that the diplobacillus, a gram-negative organism, was consistently sensitive to penicillin.

Eugene M. Blake.

Bietti, G. B., and Pegreff, G. The Weil-Felix reaction in keratoconjunc-

tivitis epizootica and in trachoma. Boll. Soc. Ital. di Biol. Sper. 1942, v. 18-21, pp. 1-2.

Coles and others have found rickettsia in the epithelial scrapings from the conjunctiva of birds in a certain form of conjunctivitis. Since some observers have reported rickettsialike bodies in trachoma, the authors tested the blood of 45 patients suffering from trachoma, by the Weil-Felix test, and found the results to be negative.

Eugene M. Blake.

✓ Bietti, G. B., and Scalfi, L. Effects of penicillin in the conjunctival sac at various intervals after its instillation. Studi Sassarese, 1945, v. 23, no. 1, pp. 1-6.

The author found that a solution containing 2,000 Oxford units per cubic centimeter instilled into the conjunctival sac every two to four hours was effective against all of the common pathogenic microorganisms of the conjunctiva. When the secretion is especially abundant and when more resistant organisms, such as Koch-Weeks and Pfeiffer bacilli, are present, more frequent use of stronger concentrations is required. Local application of penicillin in conjunctival disease is at least as effective as its intramuscular use.

Eugene M. Blake.

Davids, H. Rössler's remarks on an article: "A contribution to therapy of trachoma." Klin. M. f. Augenh., 1943, v. 109, Jan.-Feb., p. 107.

Davids defends himself against Rössler's accusation that he published his recommendation of treating trachoma with cold applications as a "new method of therapy" and also that he omitted to mention the treatment with albucid in the same article. The first publication concerning trachoma thera-

py with sulfa drugs came to Davids's knowledge after conclusion of his experiments with cold (ice, not carbon-dioxide snow) applications.

Khanolkar, V. R. **Bowen's disease of the conjunctiva.** Amer. Jour. Ophth., 1946, v. 29, May, pp. 515-519. (6 figures, references.)

Knapp, A. A. **The eye as a guide to latent nutritional deficiency diseases; a clinical study of ocular diseases at an advanced base hospital in the Southwest Pacific.** Bull. New York Acad. Med., 1946, v. 22, April, p. 217. (See section 17, Systemic diseases and parasites.)

Miller, C. D., and McIntyre, D. W. **A syndrome termed Reiter's disease (urethritis, conjunctivitis, and arthritis).** Ann. Int. Med., 1945, v. 23, Oct., p. 673.

"Reiter's disease" was not recognized as a clinical entity until 1916, when Reiter described a syndrome of urethritis, conjunctivitis, and arthritis which was nongonorrheal in nature.

This syndrome is a definite clinical entity of unknown cause, presumed to be infectious because of its clinical course. The possibility of its being a venereal disease is remote. The possibility that a virus is the etiologic factor is being investigated.

Complications are infrequent but may be very severe. The prognosis is usually good, but recurrences are noted in about one fourth of the patients. None have died.

Eye complications are infrequent. Episcleritis, iritis, and keratitis have been observed. The keratitis heals with scarring. Herpes of the conjunctiva and

cornea have also been recorded.

It must be assumed that the incidence is more frequent than appears from the literature. Since the syndrome is little known, many cases are not properly diagnosed nor recognized.

Theodore M. Shapira.

Miterstein, B., and Stern, H. J. **Treatment of acute conjunctivitis and trachoma with sulfonamides.** The Lancet, 1945, May 26, p. 649.

The acute phase of Koch-Weeks conjunctivitis is described. If left untreated, it subsides in 6 to 8 weeks, but usually becomes chronic. In 13 patients, one eye was treated with silver nitrate, the other with a 5-percent ointment of Pyranil (a compound containing p-amino-phenyl-sulphonamide in addition to pyridine-dicarboxic acid anhydride). The results in 12 cases were equally good in both eyes. Treatment with both silver nitrate and Pyranil was more successful than treatment with either alone.

Sulfanilamide by mouth, 0.05 gm. per Kg. body-weight daily, was tried without effect. However, sulfapyridine by mouth, 0.05 gm. per Kg of body weight, produced dramatic improvement within 24 hours. In a few hours the bacilli showed pleomorphic changes, and became fewer in number. After 14 hours, smears were consistently negative. Cases were clinically cured in three to seven days. Local treatment was sometimes needed. Treatment was continued at least a week beyond the time of clinical cure to avoid relapse. Sulfapyridine applied locally had no effect.

Sulfanilamide, sulfapyridine, and pyranil have proved valuable in treating trachoma. The authors think Pyranil is the treatment of choice in cases associated with severe corneal complications.

Robert N. Shaffer.

Seefelder, R. **Conjunctival scar formation in vernal catarrh.** *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 32.

It is generally accepted that vernal conjunctivitis heals without scar formation, although sometimes after many years scarring may develop. Saemisch, who was the first to describe the disease, noted in 1904 that the inflammatory process may eventually result in scar formation and atrophy. Seefelder reports the case of a man, 30 years of age, who had been under his observation for 16 years because of typical vernal conjunctivitis with eosinophilia in the blood and in the conjunctival secretion, and scar formation in the cornea. There was no trace of pannus and certainly no complicating trachoma. The tarsal conjunctiva became scarred throughout. The uniform reticular scarring, partly netlike, closely resembled trachoma. Biopsy specimen of tissue of hypertrophic conjunctival islands showed typical histologic features of conjunctivitis vernalis.

F. Nelson.

White, J. P. **Haemorrhage from the conjunctiva. Notes on a case of capillary angioma.** *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 635-637.

A case of capillary angioma on the palpebral conjunctiva of the right upper lid is reported. On two occasions the patient had suffered from bloody tears. A histologic examination of the tissue showed that the epithelium was reduced to a single row of cells where the capillaries reached it. It would appear therefore, that the angioma was the source of the hemorrhages reported by the patient. Edna M. Reynolds.

CORNEA AND SCLERA

Albanese, A. A. **Corneal vascularization in rats on a tryptophane-deficient**

diet. *Science*, 1945, v. 101, June 15, p. 619.

It has been repeatedly reported that riboflavin deficiency produces corneal vascularization in rats. The author had noted corneal vascularization in rats placed on a tryptophane-deficient diet. He then fed a control group of nine rats a tryptophane-deficient diet. Another group of nine rats was given a similar diet to which an adequate amount of riboflavin had been added. Corneal vascularization and cataracts developed at exactly the same rate in the two groups. After five weeks both groups were fed the basic tryptophane-deficient diet without riboflavin but with added tryptophane. All rats rapidly gained in weight, the corneas recovered completely and the cataracts partly disappeared.

Recent reports of corneal vascularization in man which failed to respond to riboflavin therapy suggest the possibility of an exogenous or endogenous deficiency of tryptophane and the employment of tryptophane as a therapeutic measure. Robert N. Shaffer.

Babel, Jean. **The fate of corneal transplants.** *Ophthalmologica*, 1945, v. 109, Jan., pp. 1-18.

In spite of extensive research the changes in corneal transplants still are not satisfactorily explained. The author considers only autogenous grafts as *heterogenous grafts never last long*. They are eliminated and replaced by tissue that originates in the host.

The pertinent literature is reviewed in great detail, and reports of the author's own experience are added in detail, including clinical and histologic descriptions of such cases. Among sixty corneal transplants; two corneas were examined histologically. The preparations all came from eyes in which a

second transplant was necessary, chiefly because of increasing cloudiness of the first. The author believes that the results in his eyes, despite their lack of transparency, provide some material toward a better understanding of the mechanism and the outcome in corneal grafting. The transplanted corneas which were examined histologically had been in place for periods that varied between four days and five years.

The main corneal structures, the stroma, and Bowman's and Descemet's membranes remained intact within the graft. The epithelium might be unchanged or disorganized but was different from the epithelium of the host. A necrosis of the fixed and wandering cells took place; these were replaced by other cells of unknown origin. In case of inflammation or infection, vessels from the adjoining cornea or iris invaded the transplant, bringing connective tissue and nerves into the graft, and changing its structure. Its border always remained distinct. The clinical and experimental work led to the same conclusion that the original transplant survives. It does not explain the biologic and physico-chemical conditions which sometimes keep the transplant clear and sometimes not. It is essential that the borders of the wound in the host and the margins of the graft are sharply and smoothly cut and neatly adapted to each other so as to prevent the epithelium from proliferating and growing into the wound. A careful section of Descemet's membrane is also important because remains of this membrane might give rise to obstructing layers of retrocorneal tissue. (15 tables, references.)

Blum, J. D. The heredo-familial corneal degenerations and their relation to congenital corneal opacity. (Clinical and genealogical study.) *Ophthalmologica*, 1945, v. 109, March, pp. 123-136.

The author recognizes the importance of Bueckler's paper, which brought order into the very confused nomenclature of the heredo-familial corneal dystrophies. He describes the three types of heredo-familial corneal degenerations which differ in their clinical appearance and pattern of inheritance and discusses their differentiation from other corneal abnormalities. He also reports the pedigree and clinical observations on patients with similar lesions under his care. In the discussion of differential diagnosis, lentic interstitial keratitis, epidemic keratoconjunctivitis, and corneal degeneration of Hurler's dysostosis are mentioned, and certain congenital corneal opacities are described in detail. Corneal opacities with ocular malformations, embryotoxon, and sclerophthalmia are not considered in this paper. He pays especial attention to a type of congenital corneal opacity which in its clinical picture closely resembles group 3 of Bueckler. Both lesions are familial and

recessive, they are bilateral, interstitial, denser in the center than in the periphery, with an intact epithelium and without any signs of inflammation or vascularization, and they cause considerable disturbance of vision. They differ from each other only in that the congenital opacities are present at birth and corneal dystrophies start during the first 10 years of life and progress steadily. The author reports the history, clinical appearance, and pedigree in two cases of congenital corneal opacity, and in five cases of corneal dystrophy group three. (2 pedigrees, references.)

Claus, S. Nevogenous pterygium. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 59.

A man, 41 years of age had noticed a gradually increasing gray spot in his left eye. At the limbus at the 10-o'clock position, a flat, freely movable, pigmented nevus of the conjunctiva was found associated with a pterygium which extended slightly beyond the limbus. Because of possible malignancy, the whole structure was removed and examined histologically. It proved to be a genuine nonmalignant pigmented nevus and a typical pterygium. No cellular infiltration was found in the surrounding tissue. Apparently the pterygium originated directly from the adjacent nevus, the first case of its kind to be published. (References.)

F. Nelson.

Castroviejo, R. Corneal transplantation. *Amer. Jour. Nursing*, 1946, v. 46, Jan., p. 35.

Most favorable for keratoplasty are corneas with: central opacities in which the transplant will remain surrounded by healthy tissue; keratoconus when vision cannot be improved by regular

or contact lenses or when the latter are not tolerated; and not too extensive interstitial keratitis. Less favorable are some corneal dystrophies, diffuse superficial opacities, adherent leucomas, and descemetocoeles.

Various types of operation are described. It is the opinion of the author that this operation offers no greater risk than do operations for cataract, glaucoma, and detachment of the retina. The results compare favorably with those of operations routinely practiced by ophthalmic surgeons.

Evans, C. A., and Bolin, V. S. Corneal reactions to viruses of equine encephalomyelitis after intraocular injection, *Proc. Soc. Exper. Biol. and Med.*, 1946, v. 61, Feb., p. 106.

It has been shown that injections of certain viruses produce specific reactions in ocular tissues. In these studies the viruses of western and eastern equine encephalomyelitis were injected into the anterior chambers of the eyes of rabbits. Corneal edema and opacification were produced, analogous to the toxic reaction demonstrated for the influenza virus. In general, the viruses could not be found in the aqueous after 48 hours, demonstrating that the corneal opacity is not the result of growth of the virus in the eye, even though such growth may take place to a limited

extent. As in the case of the influenza virus, large doses were required to produce the corneal reaction (the most characteristic ocular change noted). It is felt that the corneal changes are attributable to the toxic properties of the viruses used. Benjamin Milder.

Friede, R. The origin of pterygium and keratoplasty for its recurrence. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 41.

Many features in the clinical picture of pterygium are still uncertain. Whether the disease is a manifestation of a lesion of the cornea or the conjunctiva is still in dispute. Friede believes that it probably originates in the episclera, possibly under the influence of an unknown pathogenic germ. Hereditary factors, mechanical influences such as pressure of the lids, and various chemical and physical irritants may play a part in the development of pterygium. It is Friede's conviction that the operative procedures should be applied as early as possible and that simple excision is contraindicated since it may be followed by shrinkage, recurrence, and impeded ocular movements toward the temporal side. He advocates the recession of the entire structure with temporary suturing of the head to the caruncle, and closing of the conjunctival wound directly at the limbus. He believes that this is the simplest and most satisfactory operation. Transplantation of free or pedunculated flaps of conjunctiva as well as Thiersch grafts of skin and labial mucous membrane have been advocated repeatedly in order to avoid or cure recurrences. The aim of all these methods is the formation of a wall at the limbus to prevent new episcleral and conjunctival tissue from crossing the corneoscleral region. This is particularly indi-

cated when the neck of the pterygium is wide. Corneal flaps taken either from the patient's own eyes or from enucleated or cadaver eyes gave most satisfactory results in cases of recurrences. These flaps, if properly secured, heal well and quickly, before the vascularized conjunctival and episcleral tissue has time to cross. The flaps stay clear for about two weeks; later they become opaque and are completely absorbed eventually. It is important to remove as much as possible of the episcleral tissues from the posterior surface of the pterygium while performing the recession. F. Nelson.

Reis, J. L. A corneal graft operation for recurrent pterygium. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 637-640.

The common methods of pterygium operations aim at the separation and displacement of the pterygium from the cornea. This leaves an open scar of the cornea which becomes covered with conjunctiva and forms a pseudopterygium which has a tendency to grow. To prevent this complication, a modified McReynolds pterygium operation is described in which the denuded corneal area is covered by a corneal graft under a conjunctival flap.

The procedure is described in detail as it was performed on an eye with recurrent pterygium. (1 drawing.)

Smelser, G. K. The influence of vehicles and form of penicillin and sulfonamides on mitosis and healing of corneal burns. *Amer. Jour. Ophth.*, 1946, v. 29, May, pp. 541-551. (5 figures, references.)

Schaeffer, A. J. Effect of certain amino acids on healing of experimental

wounds of the cornea. *Proc. Soc. Exper. Biol. and Med.*, 1946, v. 61, Feb., p. 165.

An attempt has been made to influence regeneration of experimental wounds of the cornea, in vivo, by the administration of amino acids. In the first of a series of experiments, corneas were abraded over a measured area in both eyes of each animal. A solution which included cystine, proline, asparagin, and glutamine in saline solution was instilled in the right eye. In another series an ointment was used. In the treated eyes, healing was complete in 12 to 42 hours, whereas in the control eyes, healing took place in 55 to 120 hours. In the third group, deep corneal lesions were similarly treated, and healed in 32 to 56 hours, as compared with four to five days in the control group.

The author has used amino-acid preparations in man in the treatment of 100 corneal lesions.

Benjamin Milder.

Wright, H. B. Corneal transplantation and nursing care. *Amer. Jour. Nursing*, 1946, v. 46, Jan., p. 36.

The author, a registered nurse, describes preoperative and postoperative care in detail. Particular emphasis is placed on the mental state of the patient. Acquainting the patient with his surroundings helps to prevent the lost feeling he might have on his return from the operating room. A special stretcher is used to transfer the patient to his bed. Details of a diet intended to prevent the use of the facial muscles in chewing are given. The author advises against the use of tooth brushes, suggesting instead the use of liquid mouth washes through a tube and applicators to cleanse the teeth.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Bietti, G. B. Bilateral fissurelike pupils associated with Bitot's spots. *Studi Sassares*, 1943, v. 21, pp. 1-11.

An infant girl, aged 1½ years, presented congenital, bilateral fissured pupils, placed obliquely. There was slight light reaction and the child followed a light readily. No other congenital defects were observed, but there were xerotic triangular areas on the temporal side of the bulbar conjunctiva that resembled Bitot's spots, although there was no evidence of avitaminosis.

The condition may be unilateral or bilateral and the fissures may be parallel, oblique, vertical, or horizontal. Other congenital defects are often found in association with the pupillary defect, and heredity is occasionally a factor. A good discussion and bibliography complete the article. (1 figure.)

Blum, J. D. Indications and results from Franceschetti's corepraxy. *Ophthalmologica*, 1943, v. 106, July, pp. 1-12, and *Ophthalmologica*, 1943, v. 106, Aug., pp. 66-79.

The author considers Franceschetti's corepraxy a new and very effective method of producing an artificial pupil, especially in surgical cases of aphakia with displaced and partially occluded pupil, after postoperative complications.

He reviews the history of the surgery of the artificial pupil; mentions iridocapsulotomy and iridocapsulectomies as well as other more complicated procedures like Blaskovics's cicatricectomy; describes the surgical technique of these operations and discusses their

improvement, dangers, disadvantages.

Corepraxy is considered to be a less harmful operation in properly selected cases. It is most favorable in aphakic eyes in which the pupil is greatly displaced upward and is occluded by a membrane that is not adherent to the iris. Eyes with iris prolapse, thick, calcified, pupillary membrane, vitreous changes, or considerable corneal disease are less promising.

The surgery is performed as follows: Through a small keratome incision opposite the last remains of the pupil, a pointed hook is introduced. The hook is manipulated so as to catch the pupillary margin and bring the iris out through the incision, where it is cut by a deWecker scissors. An atrophic iris might not give way but tear instead. In this case several similar tears are made to form some kind of pupil. The resulting pupil is usually oval, in contradistinction to the slit-shaped pupil that is the result of other surgical methods. In traumatic pupillary displacements in young persons, an operation sometimes results in a thin slit, instead of the desired oval artificial pupil. It is a mistake to try to enlarge the pupil at once; more advisable to wait and to perform another corepraxy later, perpendicular to the first.

A description of 20 cases of corepraxy follows. Sixteen eyes were aphakic, two had glaucoma, and two had displaced pupils after injuries. In spite of the generally poor prognosis in this type of operation the author did not lose any eye, even when he operated on eyes which were hypotonic before the surgery. An improvement of vision resulted in 17 out of the 20 eyes; in the other three retinal detachment, hemorrhagic glaucoma, and hypotony developed. (References.)

Harley, R. D., and Wedding, E. S. Syndrome of uveitis, meningo-encephalitis, alopecia, poliosis, and dysacusia. *Amer. Jour. Ophth.*, 1946, v. 29, May, pp. 524-535. (17 figures, references.)

Icaza y Dublan, J. M. Cholesterin in the anterior chamber. *Bol. del Hosp. Oft. de Nuestra Señora de la Luz*, 1946, v. 3, Jan.-April, pp. 143-146.

The patient was a married woman of 20 years. Three years previously, some of her family had noticed that the right eye looked like a cat's eye, having a yellowish reflex. The eye was without pain. Upon examination the right iris was found to have undergone degeneration, and there was complete posterior synechia with a pupillary membrane. The intraocular pressure was above normal and there was no light perception.

The striking feature of the case was that the lower half of the anterior chamber was occupied by innumerable iridescent particles. Some of the floating crystals were needlelike, others formed plaques, some did not glisten. It is suggested that the initial stage of the formation of the cholesterin crystals had been a metastatic abscess in the vitreous, and that the general ocular disturbance had been induced by uterine infection. Several years previously, the patient had had two abortions within four months. She had since given birth to a healthy child.

W. H. Crisp.

Johnson, K. B. Metastatic carcinoma of the choroid. *Canadian Med. Assoc. Jour.*, 1946, v. 54, Jan., p. 46.

The author describes four cases of metastatic carcinoma of the choroid. In each patient the carcinoma was primary in the breast, which is the commonest site of the primary growth. In three patients metastases in other organs had not been found before those that had invaded the eye. In two, the ocular lesion had occurred seven years after the primary growth. In three, chest metastasis was eventually found. Ophthalmoscopically, a detachment of the retina extended up to the disc in all cases.

The patients live from four weeks to two years after discovery of the metastatic tumor and usually die in the fourth and fifth decade of life. The metastasis in the eye results from blood-borne emboli of tumor cells.

A flat thickening of the choroid is present, higher at the posterior pole. The vitreous remains clear, and a large detachment of the retina may occur at any time. Growth is rapid but glaucoma is late. Early pain is diagnostic.

GLAUCOMA AND OCULAR TENSION

Gradle, H. S. Preglaucoma. *Amer. Jour. Ophth.*, 1946; v. 29, May, pp. 520-523.

Paulo Filho, A., Sébas, S. R., and Giardulli, A. Siderosis bulbi. *O Hospital*, 1945, Sept., pp. 339-343 (reprint.)

Microscopic section of an enucleated eyeball in which this complication had arisen leads to the following conclusions:

The presence of an iron fragment in the anatomic elements of the anterior pole of the eyeball does not always produce siderosis bulbi. The siderosis once begun continues even after the foreign body is removed. Rarely the siderosis involves all the anatomic elements of the eyeball. It causes necrosis of the essential cells of the retina. (3 figures, references.)

W. H. Crisp.

Paulo Filho, A., and Sebas, S. R. Artificial thickening of the conjunctival flap in fistulizing operations. *Brasil-Medico*, 1945, v. 59, April 7 and 14, 9 pp. (reprint.)

The authors' technique is recommended as especially protecting against the risk of iridocyclitis. They begin the conjunctival incision near the superior fornix, cutting down to the sclera. Care is taken to carry down with the flap as much as possible of the connective tissue. Then the bulk of the subconjunctival connective tissue is separated from the conjunctiva itself, by means of scissors, and over as large an area as possible, so that this layer of tissue is accumulated at the base of the flap. After completing the other steps of the operation (whatever form of fistulizing operation is employed), and following suture of the lips of the conjunctiva, a spatula inserted at the temporal extremity of the sutured incision is used to depress the soft connective tissue down to the region of the anticipated filtration bleb. (3 figures.)

Roethth, A. de. Cyclodiathermy in treatment of glaucoma due to rubeosis iridis diabetica. *Arch. of Ophth.*, 1946, v. 35, Jan., pp. 20-22.

Rubeosis of the iris in diabetes is one of the most disastrous ocular diseases, for it usually involves both eyes and,

with rare exceptions, causes uncontrollable glaucoma. In none of the 32 cases of this disease found in the literature could miotics control the tension. The usual surgical procedures were useless, or even disastrous. The intolerable pain caused by the glaucoma necessitated enucleation in several cases. Fralick, in his excellent and comprehensive paper on this subject, reported the removal of four eyes in three cases of diabetic rubeosis of the iris. Any attempt to save some of the vision, or even the eyeball alone, is worth while.

After disappointing results with various types of operations, the author found that cyclodiathermy is the only procedure that reduces the tension in cases of glaucoma due to rubeosis. However, the treatment easily results in atrophy of the eyeball if used too extensively, particularly if both long posterior ciliary arteries are destroyed. These vessels are not damaged if the applications are made in front of the insertion of the rectus muscles as suggested by Vogt. But even if the cyclodiathermy is not done over a sufficiently large area to normalize the tension, it does alleviate the pain. Unfortunately, the progress of the damage to the retinal vessels cannot be checked.

R. W. Danielson.

Torres Estrada, Antonio. **Medical and surgical control of glaucoma.** Bol. del Hosp. Oft. de Nuestra Señora de la Luz, 1945, v. 3, Sept.-Dec., pp. 89-109.

This is a somewhat detailed consideration of the treatment of glaucoma. The author regards chronic simple glaucoma as a malady arising from a general systemic cause. He recognizes two distinct periods in development of the disease, functional and degenerative. The functional period is suscep-

tible of being treated with success in the medical field. The degenerative period calls for surgery, which should be undertaken as soon as medical care is unable to maintain adequate reduction of tension. Hemicyclodialysis is the author's surgical treatment of choice, tending to reestablish physiologic drainage of the aqueous humor. In advanced cases this operation should be combined with iridectomy. (9 figures.)

W. H. Crisp.

Torres Estrada, Antonio. **Hemicyclodialysis is an operation which reestablishes physiologic drainage of the intraocular fluids.** Bol. del Hosp. Oft. de Nuestra Señora de la Luz, 1946, v. 3, Jan.-April, pp. 121-129.

This paper, presented to the Second Pan-American Congress of Ophthalmology, Montevideo, discusses the general principles of glaucoma surgery, and urges the advantage of doing a very extensive cyclodialysis, to which the author has given the title "hemicyclodialysis," and which he considers superior to any of the filtration operations. He believes that the action of hemicyclodialysis is by opening the canal of Schlemm and the meshes of the pectinate ligament. The operation is particularly effective in the early stages of chronic simple glaucoma. The failure of any glaucoma operation is probably attributable to advanced sclerotic and degenerative changes in the pectinate ligament. (2 illustrations.)

CRYSTALLINE LENS

Geller, K. **Late traumatic rosette after contusion with Vossius's ring opacity.** Klin. M. f. Augenh., 1943, v. 109, Jan.-Feb., p. 105.

A Vossius ring combined with rosette-shaped opacities at the anterior and posterior surface of the senile nucleus was seen in the eye of a locksmith. He had had a contusion about 30 years before and his vision had become considerably impaired shortly after the injury. F. Nelson.

Goar, E. L., and Potts, C. R. The relationship of rubella in the mother to congenital cataracts in the child. *Amer. Jour. Ophth.*, 1946, v. 29, May, pp. 566-569. (References.) Also in *Trans. Amer. Ophth. Soc.*, 1945.

Prendergast, J. J. Congenital cataract and other anomalies following rubella in mother during pregnancy. *Arch. of Ophth.*, 1946, v. 35, pp. 39-41.

The reported cases of congenital defects in children born of mothers who had rubella during the first three months of pregnancy are briefly reviewed. The pathologic observations in the cases of congenital cataract and the possible significance of the time of development of these anomalies in the embryo are discussed. The results of a survey made among some of the ophthalmologists, pediatricians, and obstetricians in California to estimate the incidence of these defects in the state are reported. R. W. Danielson.

Rosen, Emanuel. Diabetic needles. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 645-653.

The author reports a characteristic lenticular opacity associated with diabetic cataract which he considers a presumptive if not a positive diagnostic sign in diabetes. The sign is not constant but when present is specific for diabetes. The sign consists of lenticular opacities in the periphery of the lens which are linear streaks no thicker

peripherally than centrally.

A series of 19 cases of diabetes is presented, all of which showed the diabetic-needle sign. Drawings of the opacities of the lens in each case are included. Many showed nuclear and cortical lens opacities as well as the diabetic needles. Edna M. Reynolds.

Rosen, Emanuel. Coppock cataract and cataracta pulverulenta centralis. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 641-644.

A report of four cases of central pulverulent cataract is given with a series of slitlamp photographs. The lesion is believed to have a strong familial tendency but the author reports having seen 24 in 18 months. There were several colored patients in this group.

The opacity occupies the most central portion of the lens and its center is somewhat transparent. It is composed of small, white dots which are highly refractile, located in the fetal nucleus.

In three of the patients, some endocrine dysfunction was noted. One patient, a man, 26 years of age, had soft, silky hair in the female pattern of distribution, adiposogenital dystrophy, and a high-pitched voice. A second patient had congenitally small kidneys and the third had an acrocyanosis.

The author recommends that the term "Coppock cataract" be dropped for this type of opacity and that an anatomically selected term be substituted. (4 figures, references.)

Edna M. Reynolds.

Szinegh, B. Anterior capsular cataract complicated by bilateral zonular cataract in a twin. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 83.

Of two identical twin brothers, seven years of age, one was normal although

slightly rachitic and retarded in development; the other had anterior polar and zonular cataracts in both eyes. He also had rickets and had suffered from frequent convulsions, possibly a manifestation of tetany, although the blood calcium was of normal value and the existence of a latent tetany could not be proved. It is most likely that the cataracts were caused by a pathologic process in early fetal life, although it is not known what kind of lesion was responsible. Cataracts that are a manifestation of a defect of the germ plasma appear in both twins. (References.)

F. Nelson.

Thannhauser, S. J. Werner's syndrome (progeria of the adult) and Rothmund's syndrome; two types of closely related heredofamilial atrophic dermatoses with juvenile cataracts and endocrine features. *Ann. Int. Med.*, 1945, v. 23, Oct., p. 559.

The symptoms of Werner's syndrome are demonstrated in case reports in the literature and in four of the author's own. With the exception of Oppenheimer and Kugel's cases, the cases of Werner's syndrome in the literature are published under the misleading designation "Scleroderma and cataracts."

The skin changes in Werner's syndrome are not those of true scleroderma. Because of its heredofamilial occurrence it is suggested that the skin changes, as the other symptoms of Werner's syndrome, are the result of a defective germplasm which does not appear until the second and third decades of life. "Progeria of the adult" is suggested as a better name since all symptoms of Werner's syndrome result in presenility of the patient.

For the skin changes a purely descriptive name, such as "heredofamilial

atrophic dermatosis with skin ulcers" seems more appropriate.

The skin ulcers in Werner's syndrome are not entirely trophic in origin. They appear only on exposed parts and are probably the result of pressure upon the thin, atrophic, and stretched skin. The healing of the ulcers by grafting skin upon the defects supports such an opinion.

The symptoms of Rothmund's syndrome are illustrated by case reports in the literature and by a case of the author's own.

The skin changes of Rothmund's syndrome are classified as "poikiloderma" or "scleropoikiloderma." Such a classification is not justified by the heredofamilial occurrence of the skin disorder nor by the histologic findings. It seems appropriate to use a simple descriptive name such as "heredofamilial atrophic dermatosis with telangiectases."

Both syndromes may occur in incomplete forms.

The heredity in both forms is recessive. The collateral occurrence in brothers and sisters of one generation is often observed. Rothmund's syndrome usually starts in childhood; Werner's syndrome in the second and third decade.

Clinical syndromes related to Werner's and Rothmund's syndromes are discussed. A chart tabulating the characteristics of Werner's and Rothmund's syndromes in comparison with related clinical entities is presented to aid in the differential diagnosis.

Cataracts are of the same kind in both syndromes. They develop as star-like opacities in the periphery of the lens, mostly at the posterior pole. However, the age at which the cataracts begin to develop is significant. In Rothmund's syndrome they are present at

the age of three to five years; in Werner's syndrome they develop in adult life, between the ages of 20 and 30 years.

That these syndromes are the result of a purely ectodermal dysplasia or a primary disturbance of endocrine function is denied. Their recessive heredity suggest that multiple defects of the germ-plasm become manifest in abiotrophic degeneration of various organs at different periods of life.

RETINA AND VITREOUS

Buxton, R. J. **Retinal haemorrhages in aplastic anaemia.** *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 632-635.

The retinal lesions found in a severe and fatal case of aplastic anemia are described and illustrated.

The patient, a male, was 28 years of age. He was admitted to a hospital after two days of illness with generalized aching, fever, and bleeding gums. He had had syphilis, and had completed two full courses of treatment with arsenic and bismuth. He had received the first injection of the third course three days before hospital admission.

The patient's blood picture showed hemoglobin 16 percent, red blood cells 750,000, white blood cells, 3,100, polymorphonuclear leucocytes 19 percent, lymphocytes 78 percent, mononuclear cells 3 percent, and very few platelets. Bleeding time was greatly prolonged. Clotting time was normal. A blood-film study showed no evidence of blood regeneration.

The ophthalmic examination showed marked pallor of the conjunctiva and in the fundus of each eye there was blur-

ring of the upper nasal edge of the optic disc. The retinal vessels were normal in size and contour. There were gross hemorrhages of three types; namely, moderate-sized, flame-shaped plaques up to 2 D.D. long, some with a yellowish center, and glistening slightly; narrow streaks, about 1 D.D. long, close to blood vessels; and two or three punctate hemorrhages in the macular areas. One small spot of exudate was noted. There was general retinal pallor and a slight degree of retinal edema surrounding the optic disc.

The patient was given a number of blood transfusions, 300 gm. of ascorbic acid daily, 2 c.c. of neohepatex intramuscularly daily, and iron and ammonium citrate.

The patient died. The post-mortem examination showed the classical picture of complete bone marrow aplasia and multiple submucous hemorrhages. (1 figure.) Edna M. Reynolds.

Easton, D. M. **Acetylcholine in the light and dark adapted frog retina.** *Proc. Soc. Exper. Biol. and Med.*, 1945, v. 59, p. 31. (See Section 3, Physiologic optics, refraction, and color vision.)

Fink, A. I. **Clinical study of effect of tobacco on the normal angioscotoma.** *Arch. of Ophth.*, 1946, v. 35, Jan., pp. 15-19.

In 1926, the classic form of the angioscotoma was first described by Evans. This work has been a source of aid to clinicians investigating disease of the nasal accessory sinuses, forms of edema, glaucoma, and menstrual disturbances. The research worker, too, has had recourse to angioscotometry in studying the effects of sulfanilamide, inhalation of oxygen, and amphetamine

sulfate, and in making studies of the effects of high altitude on the visual fields during World War II. The method has not been used, however, to determine the effect of smoking on the normal angioscotoma. Since tobacco smoking is so widespread, it was thought that knowledge of its effect might be of clinical and experimental value. It was therefore decided to study the effect of smoking one cigaret with inhalation.

The smoking of a certain popular brand of cigaret containing two percent nicotine produced a widening of the angioscotoma, cigaretts containing one tenth as much nicotine produced an alteration of the angioscotoma of lesser degree, and the controlled inhalation of an unlighted cigaret produced no alteration of the angioscotoma.

It seems probable that the effect on the angioscotoma was brought about by the nicotine. R. W. Danielson.

Hoffman, P. M. **Retinal venous thrombosis following reaction to vaccine.** *Arch. of Ophth.*, 1946, v. 35, Jan., pp. 45-46.

The uncommon occurrence of retinal periphlebitis and progressive thrombosis in a young adult following stimulating doses of vaccines with associated anaphylactoid reaction is recorded.

In the early stage the inferior temporal veins were involved, and progressive thrombotic changes in the fundus and visual fields were followed. It is of interest that the superior nasal veins, although they had presented similar early periphlebitic constrictions and exudate, did not become thrombosed, and the exudate disappeared completely. Optic neuritis occurred in the affected eye during the third week of the disease, followed one week later by a macular lesion. Ocular tension

was not notably affected during six weeks' observation of the patient.

R. W. Danielson.

Márquez, Manuel. **Technique and clinical value of hypertonic injections into Tenon's capsule for detachment of the retina.** *Monterrey Medico*, 1945, March 31, pp. 2397-2403.

Márquez says the technique here given does not appear in any book. He describes a case of retinal detachment of traumatic origin. There was a small tear at the level of the macula, through which could be seen the red color of the choroid. The tear was so small that it could not be seen in the indirect image. The detached area involved more than one half the retina, and invaded the macula. Central vision was absent.

After a preliminary anesthetic injection of 2-percent novocaine, a 15-percent solution of sodium chloride, with a small amount of novocaine was injected with a curved needle, beveled toward its concavity and the concavity directed toward the eyeball. The injection was made downward and somewhat outward, as far backward as possible in Tenon's space. Two days later the retina was found reattached, with the visual field almost entirely restored including that of the macular region, but with a slight defect below. The macular tear was closed, although the injection had not been made at its level. A similar injection was made six days later, the field continuing to gain. All that now remained of the tear was a small dark scar. The final visual acuity of this eye was 0.7: the original visual acuity was unknown. In a second case the result was unsatisfactory. OPTIC NERVE AND TOXIC AMBLYOPIAS

Bruetsch, W. L. **Malaria therapy in syphilitic optic atrophy.** *Jour. Amer. Med. Assoc.*, 1946, v. 130, Jan. 5, p. 14.

The author advocates the abandonment of intraspinal therapy in neurosyphilis because a sudden loss of vision occurs in the course of this treatment in 10 percent of the patients.

The term "tabetic optic atrophy" should be discarded and replaced by "primary syphilitic optic atrophy," be-

cause this atrophy not infrequently occurs in dementia paralytica, in meningo-vascular syphilis, and even in syphilitic persons without tabes.

The local pathologic changes are identical in the three main types of neurosyphilis. The atrophy is a chronic inflammatory process followed by nerve-fiber degeneration that starts in the intracranial portion of the nerve and spreads in both directions.

Activation of the mesodermal tissue and not the hyperpyrexia seems responsible for the arrest of the disease. Fever alone is not deleterious to the *Treponema pallidum*.

When one course of malaria does not prevent further visual loss, another course is indicated. The second course requires the use of quartan malaria since immunity to the tertian type will have taken place in the interval. Since penicillin reduces the anti-inflammatory action of malaria therapy in neurosyphilis it might be advisable to administer penicillin with the malaria treatment, or after it; to use penicillin alone would be hazardous.

In the author's post-mortem studies, the arachnoidal adhesions about the optic nerves and chiasm were not the cause of the optic-nerve degeneration in the majority of cases.

Patients in whom examination of the spinal fluid is positive for syphilis should have a yearly study of the visual field. Even though the discs may appear normal, early narrowing of the field would justify a diagnosis of beginning syphilitic primary optic atrophy. Corrective therapy for vitamin deficiency is considered of no importance in this disease.

VISUAL TRACTS AND CENTERS

Chambers, D. L. Gunshot wound of both orbits. Lancet, 1946, Jan. 19, p. 93. (See Section 16, Injuries.)

Hughes, E. B. C. Indirect injury of the optic chiasma—a case report. Brit. Jour. Ophth., 1945, v. 29, Dec., pp. 629-632.

A case of indirect injury to the optic chiasma in which operative and pathologic inspection was made, is reported. The patient, a man aged 45 years, sustained a severe craniocerebral injury as the result of an accident in which he struck his head against the windshield of a truck. There was no scalp wound but severe bruising of both orbits and frontal regions. X-ray films showed a horizontal fracture above the frontal

sinuses, with extensions vertically downwards into the right frontal sinus and into the roof of the left orbit. A posttraumatic amnesia of 24 hours' duration and a lumbar puncture, soon after injury, that showed a small amount of blood and some 60 cells per cu. mm. in the cerebrospinal fluid, indicated the severity of his cerebral injury. The neurologic signs at the time of hospital admission consisted of bilateral anosmia, loss of taste, complete facial paralysis on the right side, and a mild hemiparesis on the left side with increase of tone and of the deep reflexes. The optic discs were abnormally pale in each eye; visual acuity O.U. was 6/9, and there was complete loss of the temporal visual field in each eye.

At the time of operation for repair of the dural defect near the right frontal sinus, an excellent view of the chiasma and of both optic nerves was obtained. No gross lesion was found. No change in the appearance of the fundi or fields had occurred four months after the injury.

The author believes that the small vessels of the chiasma were damaged by stretching and that the injury to the nerves was probably secondary to this disturbance. (3 illustrations, references.)

EYEBALL AND ORBIT

Paul, Milroy. Cavernous hemangioma of the orbit successfully removed by Shugrue's operation. Brit. Jour. Ophth., 1946, v. 30, Jan., p. 35.

On a patient presenting a marked

monocular protrusion of six months' duration, a large temporo-frontal scalp flap was made. The outer rim and lateral wall of the orbit were removed and a tumor, the size of a marble, was seen within the muscle cone. It was easily shelled out and removed. The wound was closed with a minimum of deformity, and the only sequela was a limitation of lateral movement of the eye. The tumor was found to be a cavernous hemangioma. There had been surprisingly little bleeding after its removal. This method is the Shugrue operation described in Spaeth's "Ophthalmic surgery." Morris Kaplan.

Friedman, B., and Gernand, H. Sjögren's syndrome treated with stilbestrol. California and Western Medicine, 1946, v. 64, Jan., p. 31. (See Section 5, Conjunctiva.)

MacLean, A. L. Sjögren's syndrome. Johns Hopkins Hospital Bull., 1945, v. 76, May, p. 179.

Deficient lacrimation may produce a troublesome keratoconjunctivitis. The patients complain of burning, pricking, and smarting of the eyes, and occasionally of diminished visual acuity. There is a stringy discharge. The cornea often can be stained, and fine epithelial filaments may be present. There is swelling of the parotid gland and dryness of the mouth, nose, and eyes. Schirmer's test shows deficient tear production. The differential diagnosis and the theories of etiology are discussed.

The treatment consists of the use of parasympathetic stimulating agents to increase glandular secretion; the instillation of collyriums and, best of all, the occlusion of the canaliculi. Three cases of Sjögren's syndrome are described. Robert N. Shaffer.

Mattsson, Ragnor. A grain of rye as a foreign body in the upper lacrimal canaliculus. Acta Ophth., 1942, v. 20, pts. 3-4, pp. 307-309.

A farmer 27 years of age, had a purulent discharge from the right lacrimal sac, which was not relieved by a dacryocystectomy. When he was examined

a grain of rye, surrounded by granulation tissue, was found imbedded in the upper lacrimal canaliculus. After its removal, the patient had no further difficulties. It is assumed that it entered through the nose, and was forced upwards through the lacrimal sac by violent blowing of the nose. (Illustration.)

TUMORS

Claus, S. **Nevogenous pterygium.** *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 59. (See Section 6, Cornea and sclera.)

Goodman, E. G., and Iverson, L. **Chloroma, a clinico-pathologic study of two cases.** *Amer. Jour. Med. Sci.*, 1946, v. 211, Feb., p. 205.

Two patients with chloroma, both presenting symptoms and signs of a rapidly growing tumor producing extreme exophthalmos, are described. The hematologic picture was identical with that of an acute myelogenous (myeloblastic) leukemia. Chloroma may be present as small, well-circumscribed nodules, or as large, solid masses with particular predilection for meninges, periosteum, mucous membranes, endothelium, or mesothelium. The exact chemical nature of the green pigment has not been demonstrated either by spectroscopic or by polariscopic studies. It may be an intermediary product in the breakdown of hemoglobin to bilirubin. R. Grunfeld.

Mao, W. S. **Adrenal neuroblastoma.** *West China Med. Bull.*, 1945, v. 2, June 15, p. 40.

Only two cases of adrenal neuroblastoma have been reported in the Chinese literature. The case herein reported was in a child, aged three years,

first seen in the Pediatric Service of the United Hospital of the Associated Universities in Chengtu. The chief complaints were abdominal pain and swelling of the left eyelids. Subsequent examinations showed bilateral ecchymosis of the lids with exophthalmos, subconjunctival hemorrhage, and retinal hemorrhage in the left eye. General physical examination revealed lymphadenopathy, hepatomegaly, splenomegaly, and anemia. Finally the child died at home. (References.)

Paul, Milroy. **Cavernous hemangioma of the orbit successfully removed by Shugrue's operation.** *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 35. (See Section 13, Eyeball and orbit.)

Paulo Filho, A., and Sebas, S. R. **Two cases of preëpitheliomatous dyskeratosis of the cornea and conjunctiva (Bowen's disease).** *Rev. Brasileira de Cirurgia*, 1945, April (reprint).

More or less closely related to molluscum contagiosum and Paget's disease, this condition has often been called atypical chronic epithelial proliferation, and is included in the precancerous dermatoses. Clinically it appears in the form of nodules on the bulbar conjunctiva, vascular and slightly elevated, united to one another by areas of lesser density. Microscopically the epidermis presents a disorderly arrangement of cells of unequal size, with nuclei which may be large or small, clumped, fragmented, or multiple. The condition may invade the cornea, to which, however, it is loosely attached. The treatment is excision, but it may easily occur that some cells are left in place and lead to recurrence. (6 photomicrographs, references.)

INJURIES

Chambers, D. L. **Gunshot wound of both orbits.** *Lancet*, 1946, Jan. 19, p. 93.

An American soldier with a healed septic wound located in the outer half of the left infraorbital margin was admitted to the British Prisoners-of-War Hospital in February, 1945, after having been treated at various German hospitals. The vision in each eye was 6/24. Both eyeballs were intact but were not in normal position. There was some limitation of ocular movement and diplopia in all fields. X-ray examination revealed a foreign body the dimensions of which were 35 by 20 by 3 mm. and which was lodged transversely in the nose and encroached on both orbits. Removal by way of the left orbit was followed by healing by first intention, though the left antrum was filled with mucoid pus. The diplopia and limitation of movement remained but vision improved to 6/12.

Francis M. Crage.

Dansey-Browning, G. C. **Ophthalmic treatment in the field, 1943.** *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 26.

The author reports his observations on 148 wounded eyes of 129 men who were injured in the Italian campaign. Thirty-nine eyes were lost; of these 22 were hopeless at first examination. About 30 percent of the foreign bodies from German missiles were found to be magnetic. The injuries and their treatment are described individually. The liberal use of penicillin and sulfon-

amides both locally and generally is a tremendous advance in treatment. A plea is made for the "coal scuttle" type of helmet as a defense against ocular injuries.

Morris Kaplan.

Essen-Möller, Lars. **Transitory blindness after nonperforating injury to the skull.** *Acta Ophth.*, 1940, v. 20, pts. 3-4, pp. 272.

Two cases are reported. A six-year-old boy was blind for three days following a blow on the head and a short loss of consciousness. The pupillary reactions were normal. After a steady improvement in vision and in his general condition for a week, the child suddenly became unconscious, developed left-sided epileptiform spasms, with conjugate deviation to the opposite side. An exploratory craniotomy was performed because intracranial hemorrhage was suspected but none was found. The day after the operation the child was lucid and his vision was good. He was found normal on reexamination 3½ months later.

A girl, 15 years old, fell on the gymnasium floor. Six weeks after the injury she developed general neurologic symptoms, indicative of an intracranial lesion. The visual disturbances consisted of loss of visual acuity, horizontal and lateral nystagmus, outward deviation of the left eye, and slight ptosis on the left side. The fundus was normal in each eye. An exploratory craniotomy was performed through the left mastoid, because of a fracture line on the X-ray film behind the mastoid process. No abnormality was found, but the operation was followed by a rapid recovery from all symptoms.

These clinical pictures are attributed to vasomotor cerebral disturbances, caused by cerebral contusion.

Kraus, J., and Briggs, W. A. Intraocular foreign bodies. Problems of localisation and operative procedure. *Brit. Jour. Ophth.*, 1945, v. 29, Nov., pp. 557-579.

A new system of localization of radio-opaque intraocular foreign bodies is described in detail as well as an improved operative technique in stages. This method gives the position of the foreign body in the particular globe to be operated upon and also the exact position on the sclera where the incision must be made to be in closest proximity to the foreign body.

The principles of magnetism as related to the success of extracting a foreign body from the eye are discussed, and a method of regulating the diathermy apparatus to avoid complications is outlined.

A diagram of a new forceps for the extraction of nonmagnetic foreign bodies is given. (27 illustrations.)

Macaskill, J. A case of occipital lobe injury. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 626-628.

A case of injury to the right side of the back of the head in a soldier, 22 years of age, is reported. For one week after injury he could not see at all on the left side. Then objects far out on the left side became visible, but he was still aware of the blind area near the center of his vision on this side.

When examined three months after injury there was a healed depressed wound in the occipital region to the right of the midline. Both eyes were normal and had full vision. The peripheral areas of the visual fields were unimpaired, but there was a left-sided homonymous, hemianopic scotoma, with sparing of the fixation area. No other neurologic findings were present. X-ray studies showed several depressed bone fragments underlying the skull defect. Although the brain was penetrated to a considerable depth, consciousness was not disturbed. The initial loss of the whole field on the left side probably resulted from a functional disturbance of all the right visual area of the brain at the time of injury, and recovery commenced in that part of the field furthest from the injury. (Fields, references.)

Scheie, H. G., and Hodes, P. J. Injection of oxygen into Tenon's capsule. *Arch. of Ophth.*, 1946, v. 35, Jan., pp. 13-14.

Early in their experience, air, usually 6 c.c., was injected into Tenon's capsule, after which stereoscopic roentgenograms were made. Although the procedure was diagnostic and enabled one

to localize intraocular foreign bodies, it made hazardous any surgical intervention soon after the injection. The air in Tenon's capsule exerted external pressure on the eyeball and increased the incidence of loss of vitreous and prolapse of the iris. Because of this, carbon dioxide and then oxygen, both known to be absorbed more rapidly than air from tissues or closed spaces, were tried.

Air injected into Tenon's capsule was not absorbed completely for three to four days; most of it could still be seen at the end of 24 hours, and disappeared slowly thereafter. Carbon dioxide, on the other hand, was absorbed too rapidly to be effective as a contrast medium. Decreasing amounts of the gas were noted between the first and last exposure of a routine roentgenographic study. When, for technical reasons, the examination had to be repeated, there was barely enough carbon dioxide in Tenon's capsule to outline the globe.

Oxygen proved to be an ideal gas. It produced excellent visualization of the globe and was absorbed slowly enough to permit reexamination when necessary; yet the oxygen was absorbed fast enough to avoid the risk of vitreous escape at operation.

The oxygen was obtained from an ordinary oxygen tank with a sterile rubber tube which contained a cotton filter. The oxygen was allowed to flow through the tubing for several seconds, after which it was introduced directly into the barrel of the syringe through the point for attachment of the needle, displacing the plunger as it entered the barrel. The needle was then quickly applied and the injection carried out.

R. W. Danielson.

Scott, G. I., and Michaelson, I. C.
An analysis and follow up of 301 cases

of battle casualty injury to the eyes. *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 42.

A rather complete array of facts and figures concerning 359 eyes injured in the Western Desert Campaign is presented, mostly in tabular form. Fifty-six eyes were enucleated within 2 to 3 days after injury; of the others, 190 had penetrating wounds, 52 had contused wounds, and 26 were injured by concussion. Grenades accounted for 25 percent of wounds, shells 24 percent, and gun shot 11 percent. Infection was minimal, whether penicillin or sulfonamides were used or not, and apparently these drugs were used very little. No cases of sympathetic ophthalmia occurred. Sixty-three percent of the men were returned to their units (loss of an eye did not make a man unfit for overseas service). Twenty percent had a final visual acuity of 6/12 or better, while 38 percent could only count fingers or less (half of this defective vision was probably due to cataract). Vitreous hemorrhage caused 60 percent of the defective vision below 6/60 and cataract 18 percent. Of the intraocular foreign bodies, 37 percent entered through the cornea, 33 percent the limbus and 25 percent the sclera. X-ray localization was accomplished by limbal rings sewed to the sclera. This method failed in only three cases, and in each the foreign body was behind the eye. Twenty eyes suffered double penetration, and retinal separation resulted in four of them. Concussion was much less destructive than contusion, and perforation was considerably more serious than either.

Morris Kaplan.

Struble, G. C., and Kreft, A. J. War injuries of the eyes and visual pathways. *War Med.*, 1945, v. 8, Nov.-Dec., p. 290.

In World War I wounds of the eyes formed eight percent of all injuries, although the exposed surface of the eyes is only one four-hundredths of the total surface of the body. No figures for the present war are available. Factors accounting for this high figure are listed, and the nonocular wounds which affect the visual pathways are described in some detail. In 1918, Lagrange described a set of "laws" showing a constant, almost mathematical relationship between the type of orbital wound and the resultant type of ocular lesion. These rules apparently are just as applicable today, and several case reports are presented which bear this out. A strong plea is made for field studies of every patient receiving penetrating wounds of the head.

Included in the article is an interesting discussion of ballistics of wounds. A 115-grain Springfield rifle bullet leaves the gun with a velocity of 2,700 feet per second and rotates on its long axis 3,000 times per second. As it enters tissue it wobbles, often as much as 90 degrees. Its wounding effect is roughly 20,000 horsepower. Morris Kaplan.

Zorab, E. C. War surgery of the eye in forward areas. *Brit. Jour. Ophth.*, 1945, v. 29, Nov., pp. 579-593.

A description of the work done in a mobile ophthalmic unit in the Mediterranean theatre of war is given and surgical procedures adopted in dealing with various eye injuries are outlined. An analysis of the 440 battle casualties requiring major operations between October, 1943, and October, 1944, is given. Twenty-eight and seven tenths percent of these eyes were irreparably damaged and removed. The brain was involved in 6 percent of the injuries and the accessory sinuses were involved

in 12 percent. Panophthalmitis supervened in only 2.5 percent. Of 208 repairable eyes, 80 percent contained intraocular foreign bodies. In 43 percent of these the foreign bodies were removed by magnet; 16.7 percent were removed by the anterior route, 14.4 percent by the posterior route, and 69 percent through the wound of entry. Intraocular foreign bodies were removed by means other than the magnet in 10.8 percent. In 46 percent the intraocular foreign body was not removed.

SYSTEMIC DISEASES AND PARASITES

Arce, J. L. G. The problem of diabetes in ophthalmology. *Bol. del Hosp. Oft. de Nuestra Señora de la Luz*, 1945, v. 3, Sept.-Dec., pp. 110-120.

This general review of the subject deals with conditions in the eye directly resulting from diabetes and with the care to be taken of diabetic patients who require ocular surgery.

W. H. Crisp.

Bietti, G. B. Fuller application of compulsory insurance against tuberculosis in the field of ophthalmology. *Trans. Soc. Oftal. Ital.*, v. 8, pp. 5-9.

Bietti urges greater use of tuberculosis sanatoriums in the treatment of ocular tuberculosis, especially in uveitis. Good results were reported from German and Swiss institutions from this treatment. Laws were passed in Italy in 1927, providing for insurance against tuberculosis and for the provision for such sanatoriums. From 0.5 to 2 percent of all clinic admissions are considered to be due to tuberculosis.

Favorable location of institutions, rest, good food, and removal from infected members of the family account for the better results of treatment of ocular tuberculosis. Eugene M. Blake.

Buxton, R. J. Retinal haemorrhages in aplastic anaemia. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 632-635. (See Section 10, Retina and vitreous.)

Dansey-Browning, G. C., and Rich, W. M. Ocular signs in the prisoner of war returned from the Far East. *Brit. Med. Jour.*, 1946, v. 1, Jan. 5, p. 20.

Ocular studies were made on 30 prisoners who had suffered from dysentery (26 cases), malaria (15 cases), and beriberi (27 cases).

Ten cases of beriberi were discussed. The patients showed the following significant changes: Five had a color scotoma, and in five corrected vision was only 6/60. There was some pallor of the optic disc in both eyes of each patient; four had apparent primary optic atrophy, four showed pallor of the papillomacular bundle, and eight showed temporal pallor. In eight of the 10 patients there was evidence of bilateral retrobulbar neuritis, with a characteristic scotoma for white, but no peripheral constriction of the field or ocular-muscle paresis.

The author discusses the pathology, prognosis, and treatment of "dry" beriberi and vitamin deficiency.

There is a relationship between the scotoma of beriberi and that of toxic amblyopia. Deficiency of vitamins B₁ and B₂ plays a part in the ocular signs of beriberi, but the exact nature of the nutritional neuritis produced remains obscure.

The bilateral optic-nerve degeneration in this disease is more common

than the literature leads one to believe, and though increased vitamin-B₁ intake improves peripheral nerve symptoms, the damage to the optic nerve is permanent. Francis M. Crage.

Donegan, E. A. Ocular findings in tropical typhus. *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 11.

Ocular findings in 101 cases of tsutsugamushi fever or scrub typhus in the India-Burma campaign are described. Conjunctival hyperemia, vitreous haze, mild hyperemia of the optic disc, and occasionally edema of the disc were seen. These signs persisted for two to three weeks and subsided.

Morris Kaplan.

Fanta, H. Eye lesions in spotted typhus. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 11.

Fanta reports the ocular lesions observed in a large number of patients (no figures given) in an army hospital in Poland. They were examined systematically during the period of fever and during convalescence. These examinations proved, contrary to various previous communications, that eye lesions are very common in spotted typhus and that practically all parts of the eye can be involved. In the beginning and during the course of the fever eye complications are often overlooked because of the severity of the general disease, and the absence of subjective eye disturbances. The first symptom is a conjunctival injection, and secretion is almost invariably present. It does not respond to treatment but usually disappears toward the end of convalescence, although about 10 percent of all patients suffer from a certain catarrhal condition for several weeks. In 87 percent of all cases there was a typical roseolar

rash in the lower fornix. Corneal lesions do not occur during the fever period; epithelial lesions with slightly diminished visual acuity occurred in only two patients. Iritis was observed in four patients during convalescence. Cataract was not seen, but moderate vitreous opacities occurred quite frequently. A few days after the onset of fever noticeable engorgement of retinal veins could be observed almost invariably, and it persisted for a long time, whereas changes of arterial vessels usually were absent during that period. During convalescence the arteries often showed typical signs of hypertension (silver-wire arteries, differences in caliber) accompanied by general hypertension. Petechial retinal hemorrhages along retinal vessels, usually in the periphery of the fundus and never noticed by the patient, were common. Measurements of the blood pressure in the central retinal artery often showed a marked hypotension especially in patients with dimmed consciousness; this suggests connection with the encephalitic process which is often present. One patient suffered an extensive hemorrhage in the macula of one eye which caused a central scotoma and probably permanent damage. Blurring of the discs, starting during the fever period and often persisting through convalescence, was very common. In 40 percent of such patients the vision was moderately diminished and central scotoma for red and green was present. Fanta ascribes this defect to optic neuritis, in some of the patients, to true papilledema in others, and in some to a combination of both. Transient convergence pareses, often requiring prismatic corrections, occurred occasionally, and some doubtful cases of accommodative defects were observed. Dur-

ing the convalescent period many patients show a certain nervous irritability often accompanied by marked mydriasis, causing photophobia. Night blindness was never observed. (References.)
F. Nelson.

Grant, W. M. Ocular complications of malaria. *Arch. of Ophth.*, 1946, v. 35, Jan., pp. 48-54.

Dendritic, or herpetic, keratitis is believed to be the most frequent ocular complication of malaria.

A type of corneal lesion referred to by most authors is described as a monocular interstitial process with clouding of the stroma but without vascularization.

A major proportion of the ocular complications which have been described in association with malaria are due to vascular and neurologic lesions. Lesions that result in loss of vision and are evident ophthalmoscopically are optic neuritis, atrophy of the optic nerve, and degenerative or hemorrhagic lesions of the retina and choroid.

Malaria may incite several characteristic disturbances in various parts of the eye. The lesions are usually monocular but moderately incapacitating. The relatively frequent complication of herpetic keratitis is nonspecific and several of the disturbances appear to be best explained on the basis of vascular lesions attributable to the malarial parasites. Lesions of the choroid, retina, and optic nerve, which from histologic evidence appear to be due to emboli of parasitized cells and which are commonly bilateral, are the most serious of the complications, because of their interference with vision. Treatment with antimalarial drugs has in general been successful in all the ocular disturbances except herpetic kera-

titis, which is caused by a virus, and for which specific chemotherapy is lacking.

R. W. Danielson.

Knapp, A. A. The eye as a guide to latent nutritional deficiency diseases: a clinical study of ocular diseases at an advanced base hospital in the Southwest Pacific. *Bull. New York Acad. Med.*, 1946, v. 22, April, p. 217.

A group of service men who had subsisted on a restricted diet, mostly canned foods, for 6 to 18 months in the Southwest Pacific, were studied. The most common complaint was impairment of vision, and homatropine refractions revealed axial myopia of +0.25 to +1.25 diopters. Many men complained of "inflamed eyes," and all were found to have mild vernal catarrh. The author implies that allergic conjunctivitis has a nutritional basis, and cites previous experiments in which this condition was helped by the use of calcium and vitamin D. A third complaint was "night blindness."

Objectively, the author noted blurring of the discs and a hazy fundus, but found normal blind spots, and normal perception of form and color. He believes that the fundoscopic findings mentioned may be signs of a latent deficiency state. In some patients enlargement of the blind spots with or without pallor of the disc was observed. The author ascribes these findings to retrobulbar neuritis, and states that the patients recovered after treatment of infectious foci and a nutritious diet. Chorioretinitis near the fovea was also reported; visual acuity in these patients was normal.

All the subjects of the study appeared healthy in other respects. Those with vernal catarrh, enlarged blind spots, pallor of the disc, and chorioretinitis are reported to have re-

sponded rapidly to diet. Neither the deficient diets nor the therapeutic diets which improved the patients were analyzed qualitatively or quantitatively.

Benjamin Milder.

Macaskill, J. Some ocular complications of scrub typhus. *Brit. Jour. Ophth.*, 1945, v. 29, Oct., pp. 537-540.

Scrub typhus is one of the typhus fevers endemic in Eastern Asia, due to larval mites that abound in areas of scrub jungle. The clinical features of the disease are fever, severe toxemia, headache, and prostration. Some patients become unconscious and others mentally disoriented. Diffuse glandular enlargement and a maculo-papular rash are common. The mortality rate is 10 to 15 percent. The Weil-Felix reaction is positive about the tenth day of the illness.

The essential pathologic change is a generalized vasculitis affecting the arterioles and smaller vessels. This results in destruction of the vessel walls with extravasation of blood into the surrounding tissues and vascular blockage either by thrombosis or cellular infiltrations. The lesions are patchily distributed throughout all organs and the central nervous system. Generalized congestion of the brain and meninges is commonly seen at post-mortem examination.

The ocular complications of 70 cases occurring in Assam are reviewed. Congestion of the conjunctiva occurred invariably in the acute phase of the disease. Subconjunctival hemorrhages were seen in four cases; in one there were extensive bilateral hemorrhages. Marked engorgement of the retinal vessels was noted in seven cases. Papilledema was present in four patients, and was bilateral in three of them. In these three there was an in-

crease in intracranial pressure associated with an increase in the protein content of the cerebrospinal fluid. Retinal hemorrhages occurred in four cases. One case of bilateral optic atrophy was seen six months after the acute stage of illness.

The visual fields of the patient with optic atrophy are given and the course of his illness is described. The author believes that the optic atrophy was toxic in origin, and he mentions that many patients have a nerve deafness, that is probably also toxic in origin. (Fields.) Edna M. Reynolds.

Miller, C. D., and McIntyre, D. W. A syndrome termed Reiter's disease (urethritis, conjunctivitis, and arthritis). *Ann. Int. Med.*, 1945, v. 23, Oct., p. 673. (See Section 5, Conjunctiva.)

Posner, M., and Horrax, J. Eye signs in pineal tumors. *Neurosurgery*, 1946, v. 3, January, p. 15.

Pineal tumor is rare. Its symptoms resemble closely those of cerebellar neoplasm. An exact evaluation of characteristic eye signs and ventriculograms, however, lead to an early, correct diagnosis. Subtemporal decompression followed by irradiation is satisfactory therapy.

Compression and obstruction of the aqueduct of Sylvius will cause headache, nausea, vomiting, and papilledema. Pressure of the tumor on the corpora quadrigemina results in central deafness and gives rise to the following eye signs; (1) impaired pupillary reactions; (2) limitations of extraocular movements, especially conjugate movements upward; (3) nystagmus; (4) strabismus. Pressure on the tentorium gives rise to cerebellar signs. General examination often reveals endoc-

rine dysfunction in the form of macrogenitosomia praecox, diabetes insipidus or dystrophia adiposogenitalis.

In 16 cases of pineal tumor, dilated pupils were present in 31 percent; there was impaired reaction to light in 50 percent; reaction of the pupils in accommodation was impaired in 12 percent; papilledema was present in 56 percent; and upward gaze was limited in 31 percent. R. Grunfeld.

Ridley, Harold. Ocular manifestations of malnutrition in released prisoners of war from Thailand. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 613-618.

A report of the examinations of the eyes of 500 released allied prisoners of war and internees from Thailand, whose sight had deteriorated during captivity, is given. The food was inadequate in quantity and deficient in protein, fats, and vitamins. The three daily meals were the same and consisted almost entirely of carbohydrates. From October, 1942, to March, 1943, everyone was forced to labor from dawn to dusk on building the Bangkok-Moulmein railway. The food was reduced to starvation level, and for a time only rice and salt were supplied. Most of the visual disorders originated during or shortly after this period.

One hundred of these patients were amblyopic. In many of them the onset was sudden, and maximum disability was reached within a single day, but in others it was gradual, taking months to develop. Rather surprisingly there were few complaints of hemeralopia. Intercurrent infections tended to precipitate amblyopia. Many patients with amblyopia also suffered from pellagra, edema of the legs, beriberi, sore tongue, and perleche. Quite a high proportion of the amblyopic were also nerve deaf. There were 48 cases of optic

atrophy and 30 were regarded as doubtful. In some instances of severe and prolonged amblyopia, no abnormalities were visible.

Campimetry in 90 patients revealed a small, sharply demarcated central scotoma, very dense but rarely more than 3 degrees and often only 1 degree or less from the fixation point. In the majority of these cases, there was a history of considerable improvement during captivity.

Practically all the released prisoners showed some degree of keratoconjunctival abnormality. In 96 percent of the amblyopic patients and in 91 percent of the other patients there was limbal vascularization accompanied by opacification. The limbal capillaries frequently formed aneurysms so large that they could be mistaken for hemorrhages.

All the ex-prisoners were unduly presbyopic.

Amblyopic patients are still arriving at the rate of about five in a day, and it is possible that 1 percent of the survivors from Japanese prison camps may be permanently disabled by defective sight.

Rosen, Emanuel. Diabetic needles. *Brit. Jour. Ophth.*, 1945, v. 29, Dec., pp. 645-653. (See Section 9, Crystalline lens.)

Semadeni, B. Histological findings in a patient with numerous microfilarias in both eyes. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 35.

A man, 39 years of age, who had spent the years 1936 and 1937 in the Sudan and Algeria, developed burning and redness of the eyes, zoster-like skin eruptions that suggested herpes zoster, disturbances of temperature sense, swellings about nose and ears, diarrhea,

and night sweats. In 1939, an eosinophilia of 28 percent was detected and a slitlamp examination revealed about 300 live microfilarias, 0.2 mm. in length, in the anterior portion of the parenchyma of each cornea. Five to 20 of the parasites could be observed in active movement in the aqueous, especially after exposure of the eye to light (positive phototropism.) In excised pieces of skin from the ear and neck the parasites could be identified histologically as larvae of *Onchocerca volvulus*. Nowhere could the adult parasites be detected. Various therapeutic measures were applied unsuccessfully. The patient died after an accident in October, 1941. Histologic examination of the eyes showed cellular infiltrations in the cornea, conjunctiva, episclera, and the superficial layers of the sclera; also a little in the ora serrata and the choroid. The parasites are most numerous in the eye where lymph spaces are found.

F. Nelson.

Sautter, Hans. Spotted typhus and eye. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 24.

The clinical records of two patients with simple unilateral incomplete optic atrophy with contraction of visual fields after spotted typhus are reported. The histologic findings in three pairs of eyes enculeated *post mortem* are also reported; the conjunctiva was hyperemic, there was subepithelial, cellular lymphocytic infiltration, and an increase in number of beaker cells. Similar cellular infiltration was found in the iris and ciliary body, but there was no exudation into the anterior chamber and vitreous body. In all specimens the choroid was hyperemic, thickened, and massively infiltrated, chiefly in the choriocapillaris. There were incipient thrombi in some veins. Invariably a

strong cellular infiltration was found in the optic nerve and its sheath, and papilledema, which spread into the retina. The latter was hyperemic in the vicinity of the nerve head. Hemorrhages and other changes were usually absent in the retina. An infiltrative retinal focus was found in only one eye. The muscles also showed small-celled interstitial, perivascular infiltration. (References.) F. Nelson.

Sen, K., and Ghose, N. Ocular gnathostomiasis. *Brit. Jour. Ophth.*, v. 29, Dec., 1945, pp. 618-626.

A case of gnathostoma in the human eye is reported. A brief description of the life cycle and habitat of the worm is given.

The patient was a Hindu Brahmin, 26 years of age, who was admitted into the Eye Infirmary for treatment of orbital cellulitis with hemorrhages in the retina and the vitreous of his left eye.

He reported that 10 days before admission he had felt a dull aching pain on the left side of his nose. The next day the pain increased, and an itching swelling appeared on the left cheek and lower eyelid. It increased until he could not open his left eye.

Examination revealed chemosis of the conjunctiva and restriction of movements of the eyeball. The pupil was dilated and reacted to light sluggishly. The tension was normal, and the vision 6/6. The right eye was normal. Two days later the swelling of the lids and the chemosis of the conjunctiva had almost disappeared, but the pain was more severe in the eye, and the vision was reduced to perception of hand movements. The fundus showed a hazy vitreous with engorgement of the retinal veins and hemorrhages in the retina. The patient was admitted to the hospital. General examination re-

vealed a moderate anemia and slight eosinophilia. He developed an iritis which responded to the usual treatment, but later the iritis recurred with increased tension and one of the nodules in the iris was seen to be moving. Slitlamp examination showed the presence of a worm in the eye. This was removed and found to be about 4 mm. long and completely covered with iris pigment.

When it was possible to see the fundus, a circular gray area below the macula was made out, probably the site of the worm's entrance into the eye.

The patient made an uneventful recovery but optic atrophy developed. (3 illustrations, references.)

Thannhauser, S. J. Werner's syndrome (Progeria of the adult) and Rothmund's syndrome; two types of closely related heredofamilial atrophic dermatoses with juvenile cataracts and endocrine features. *Ann. Int. Med.*, 1945, v. 23, Oct., p. 559. (See section 9, Crystalline lens.)

Zeeman, W. P. C. Gargoylism. *Acta Ophth.*, 1942, v. 20, pt. 1, pp. 40-47.

A child, aged 6½ years, with gargoylism came to autopsy. The lesions in the central nervous system resembled those of amaurotic family idiocy. The corneal lesion, which is described in detail, is strikingly similar to that reported by Berliner, in 1939, under the name of lipin keratitis of Hurler's syndrome (6 photomicrographs).

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Ayesworth, F. A. Causes of blindness in over 12,000 cases. Canadian

Med. Assoc. Jour., 1946, v. 54, Jan., p. 30.

In this blind population the visual acuity varies from no light perception to 6/60. The latter is the upper limit for economic blindness accepted by the pension authorities.

Both topographic and etiologic classifications are given. Glaucoma is the cause of the largest number of cases of blindness and myopia of the second largest. Numerous other causes are mentioned.

The author suggests that every individual between the ages of 40 and 50 years undergo an examination under a cycloplegic for early diagnosis and prophylaxis against blindness.

Francis M. Crage.

Fishenden, R. B. Types, paper, and printing in relation to eyestrain. Brit. Jour. Ophth., 1946, v. 30, Jan., p. 20.

A description of the various types of lettering used in printing (in England) and of the effects of various kinds of paper on legibility is presented. Some of the details of the lettering are analyzed. No definite conclusions as to the effect on eyestrain or on vision seem to have been reached.

Morris Kaplan.

Fox, M. J., and Bortin, M. M. Rubella in pregnancy causing malformations in newborn. Jour. Amer. Med. Assoc., 1946, v. 130, March 2, pp. 568-569.

The writers' investigation is based on the records of the Public Health department of the city of Milwaukee. It covers a 3-year period and includes all married women who were pregnant at the time they had rubella. The results of investigations of the occurrence of congenital malformation in babies born by mothers who had rubella in the early months of pregnancy appears

in tabulated form. The writers state that their records do not justify the termination of pregnancy in women who have rubella. The occurrence of congenital malformations in virus diseases in pregnant women is, however, a subject worthy of further careful investigation.

M. Lombardo.

Hathaway, Winifred. The partially seeing child in 1950. Sight-Saving Rev., 1945, v. 15, Fall, p. 156.

The author sees much hope for the visually handicapped child, whose number will probably decrease now that most states have sane premarital and prenatal laws. Interstitial keratitis and ophthalmia neonatorum may be expected to disappear, and with sulfonamides, penicillin, and corneal transplants widely used few children should be sightless. Increased research in nutrition and in lighting should also bring benefit. Better training of teachers is predicted, and increased use of sound and radio in teaching should make the education of the visually handicapped equal to that of the normal child.

Morris Kaplan.

Henderson, J. W. Overseas ophthalmology. Amer. Jour. Ophth., 1946, v. 29, May, pp. 551-562.

Nicholls, J. V.V. Ophthalmic status of Cree Indians. Canadian Med. Assoc. Jour., 1946, v. 54, April, p. 344.

Three hundred Cree Indians, of Northern Manitoba, were surveyed to determine the type and frequency of ocular diseases. These people are subjected to prolonged exposure to cold and wind, and subsist on a diet poor in fresh vegetables, dairy products, and meat. The most frequent abnormality was pterygium, and its incidence increased with each decade. Pinguecula was common; retinal arteriosclerosis

was rare. A relatively greater incidence of visual defects among the adults of the group, as compared with other adult groups, was ascribed to the higher percentage of organic ocular disease.

Benjamin Milder.

Minton, Joseph. *The one-eyed worker*. *Sight-Saving Rev.*, 1945, v. 15, Fall, p. 161.

One-eyed people are divided into two groups: those who have lost an eye in childhood, and those who have lost an eye in adult life through disease or injury. The first group is not handicapped, whereas the second group has much readjusting to accomplish. Most men interviewed (at the Royal Eye Hospital, London) had lost an eye while hammering, chipping, boring, or milling. The most difficult part of readjustment was that involving depth perception, although all, sooner or later, apparently overcome this problem. If the lost eye was the dominant eye the problem is greatly exaggerated; it is equally minimized if the dominant eye is retained. The author discusses reemployment opportunities and stoutly insists that, although the one-eyed worker is actually fit for most jobs, the safety of the remaining eye should be the first consideration, and he should certainly not be returned to his previous job if the likelihood of injury remains.

Morris Kaplan.

Queiroga, Geraldo. *Teaching of ophthalmology in the United States*. *Rev. Brasileira de Oft.*, 1945, v. 4, Dec., pp. 77-88. (See *Amer. Jour. Ophth.*, 1946, v. 29, p. 512.)

Rycroft, B. W. *Ophthalmology in the B.N.A. and C.M. forces*. *Brit. Jour. Ophth.*, 1945, v. 29, Nov., pp. 594-607.

A description of the military admin-

istration of the campaign in North Africa is given. The ocular diseases related to the terrain and the subtropical climate of North Africa are discussed, and methods of treatment are outlined. The treatment of battle casualties is also described.

The changes made in the ophthalmic and optical services in the campaign in Sicily and Italy are described, and the memorandum which was issued to medical officers for the preliminary care of ophthalmic cases is given together with the general and special instructions to medical officers for the care of eyes.

The Livingstone hand electromagnet and a portable giant-magnet stand, as well as the antimine perspex visor, are examples of the successful research that was carried out during the campaigns.

In the Sicilian and Italian campaigns the giant magnet was applied to all penetrating wounds of the eye as soon as possible after injury. In this way, 50 to 60 percent of all magnetizable foreign bodies were removed in good time.

Deep intraocular infections were treated with penicillin, which is a great advance in the prevention and treatment of ocular sepsis.

The Lister frill excision for disorganized eyes was carried out when these were seen at an early stage. At later stages, enucleation with the implantation of a 14-mm. perspex globe in Tenon's capsule was done. The old evisceration operation was practically discarded, and enucleation alone was very infrequent. To clean up dirty sockets, 2-percent silver nitrate paint and penicillin together with adhesive straps on the upper lid to allow the ingress of air proved very successful. (5 illustrations.) Edna M. Reynolds.

"Screening," eye examinations, and follow-up. *Sight-Saving Rev.*, 1945, v. 15, Fall, p. 132.

A comprehensive public-health eye program for large groups is presented. The program includes early discovery through periodic screening of groups of individuals, comprehensive eye examination for each one who seems to have any visual or eye difficulty, and a follow-up system to aid in securing eye examinations and in carrying out recommendations.

Screening tests suggested are: Snellen test for distance, plus-lens test for hyperopia, tests for near vision, rough

visual fields, muscle balance, color vision, depth-perception tests, and stereoscopic-vision test. That the accomplishment of all these on all the people would be extremely difficult is admitted, but it is an ideal to strive for.

NEWS ITEMS.

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month.

DEATHS

Dr. William Byron Agan, Brooklyn, New York, died February 5, 1946, aged 58 years.

Dr. M. Fullenwider, Muskogee, Oklahoma, died January 26, 1946, aged 67 years.

Dr. Edward Stieren, Pittsburgh, Pennsylvania, died January 8, 1946, aged 72 years.

Dr. James Watson White, Albany, New York, died May 15, 1946, aged 69 years.

MISCELLANEOUS

Four scholarships for the advanced study of eye diseases at New York University College of Medicine will be provided annually by the Lions Club of New York, it was announced May 14th. The scholarships will be valued at \$500 each and will be available to four graduate medical students to be selected by the department of ophthalmology of the medical school, enabling them to have a year of advanced study.

The Rochester Orthoptic Center is receiving applications for its next training course for orthoptic technicians. This course is accredited by the American Orthoptic Council. Information may be received from the Rochester Orthoptic Center, 208 North Goodman Street, Rochester 7, New York.

The Post-Graduate School of the University of Southern California School of Medicine is presenting a six-months' basic course in ophthalmology starting May 20th. Dr. A. Ray Irvine, professor of ophthalmology, is director of the course; he is assisted by Drs. Maurice Beigelman, William Endres, and S. Rodman Irvine.

The entire first month was devoted to pre-clinical courses organized as follows: Anatomy, Dr. Paul R. Patek; Physiology, Dr. Douglas Drury; Pathology, Dr. Ernest Hall; Bacteriology, Dr. John F. Kessel; Pharmacology, Dr. Clinton Thienes; Biochemistry, Dr. Harry Deuel, Jr. During the *second month* mornings are devoted to Histopathology and afternoons to intensive work in Physiological optics.

The *3d, 4th, and 5th* months will stress Clinical ophthalmology and Refraction. Clinical instructors include: Drs. C. H. Albaugh, Louis Bloomberg, John Bullis, Daniel B. Esterly, Channing Hale, Deane C. Hartman, W. C. Irvine, Raphael Koff, George B. Landegger, John P. Lordan, Henry R. Nesburn, Robert A. Norene, M. W. Nugent, Stephen Popovich, Helen Preston, Alfred R. Robbins, Carroll Weeks, Clinton A. Wilson, Warren C. Wilson,

Miss Dorothy Franklin, Mr. Russell Stimson, and Miss Dorothy Bergin.

Dr. Dwight Trowbridge of Fresno will be responsible for the section on Neuroophthalmology. The *6th month* will be spent in review with emphasis on preparation for the American Board Examinations.

Problem cases in Refraction and Therapeutics will be presented. Among several nationally known ophthalmologists who will be available during this final month for short series of lectures are Dr. Phillips Thygeson and Dr. Meyer Wiener. Examinations will be given at the end of each month. Sixteen students are enrolled, all of them returned service men. Enrollment was limited mainly by restricted facilities for work in refraction. Coöperation of the administrative and eye staffs of the Los Angeles County General Hospital is appreciated as essential to the success of the course.

As the guest of Emory University, 155 ophthalmologists from 19 states gathered recently at a unique and outstanding ophthalmologic seminar honoring the memory of Dr. Abner Wellborn Calhoun.

The University invited six of the nation's prominent ophthalmologists to be its guest speakers during the three-day session opening April 4th. Their presence in addition to that of the other guests was testimony to the memory of Dr. Calhoun, the first teacher of ophthalmology in the South and an outstanding ophthalmologist until his death in 1910. He was a professor of ophthalmology and otolaryngology in the Atlanta Medical College, which later became affiliated with Emory University, and the University chose this unique seminar to honor his memory.

During the three days 15 papers on ophthalmologic subjects were presented. The guests were entertained at luncheons and dinners by the University, the Board of Trustees of Grady Hospital, and by the University's Department of Ophthalmology.

At the opening dinner, Dr. Frank B. Walsh, associate professor of ophthalmology at Johns Hopkins University, presented a paper on "Myasthenia gravis." Following was an address on "Medical ophthalmology" by Dr. Walter I. Lillic, professor of ophthalmology at Temple University.

The April 5th session opened at Grady Municipal Hospital with which Emory University is affiliated and at which it does most of its bedside medical teaching. Before an audience which

overflowed the new Colored Nurses' Auditorium, Dr. William Benedict, chief of the Eye Section of the Mayo Clinic, presented a paper on "The clinical meaning of exophthalmos."

A noon recess permitted the entire group to inspect the Emory University department of ophthalmology at Grady Hospital, including the well-organized Colored Eye Department and the eye clinic in the white section. They also inspected the complete eye pathologic laboratory, one of the first in the South. The department has a chief, four assistant professors, four instructors, plus one full-time instructor; it is combined with ear, nose, and throat work. (Its three-year service with six men on the services gives outstanding training to its graduates.)

At the Academy of Medicine, Dr. Derrick Vail, professor of ophthalmology at Northwestern University, presented his paper on "Eye changes in diabetes," followed by Dr. Frank B. Walsh speaking on "Naso-pharyngeal tumors."

After a dinner as guests of Emory University, the 152 attendants heard Dr. Parker Heath, professor of ophthalmology at Wayne University, deliver a paper on "Ocular therapeutics in glaucoma." He was followed by Dr. John Dunnington, professor of ophthalmology of the College of Physicians and Surgeons, Columbia University, whose subject was "The treatment of detachment of the retina."

On the final morning Dr. Benedict spoke on "Glaucoma in diabetes," and Dr. Dunnington on the "Surgical treatment of the vertical deviations." The University's ophthalmology department was host at a luncheon.

Afternoon papers were delivered by Drs. Heath, Walsh, and Lillie. That evening Dr. Benedict spoke on "Preparation of the patient for cataract operation," and Dr. Vail on "The circulation of the optic nerve and its influence on disease."

The entire meeting was said to be remarkable in the uniformly high attendance by all guests. It was one of the rare seminars sponsored in the South by an entire university rather than exclusively by one individual or department.

The thirty-second annual meeting of the Oxford Ophthalmological Congress was held on July 4 to 6, 1946, at the Department of Human Anatomy, Oxford, by kind permission of Prof. Le Gros Clark. Accommodation was secured at Keble College, and the Warden kindly agreed to include lady members as residents in College. Members met informally at supper on Wednesday, July 3d, at 7:45 p.m. in the Hall of Keble.

The Congress opened with a discussion on "Amblyopia" led by Mr. Philip Jameson-Evans and Mrs. Dorothy Campbell. The Doane Memorial Lecture, entitled "The state of the retina in diabetes mellitus," was delivered by Prof.

Arthur J. Ballantyne. Facilities were provided in the Museum for demonstrations, and members were invited to bring forward cases, specimens, instruments, apparatus, and other matters, of ophthalmologic interest. Orthoptists were granted the privilege of attending the Congress as visitors on invitation of a member at sessions in which subjects affecting their department were discussed.

SOCIETIES

The following officers were recently elected by the New York Society for Clinical Ophthalmology: president, Dr. Benjamin Friedman; vice-president, Dr. Daniel Kravitz; recording secretary, Dr. Bernard Kronenberg; corresponding secretary, Dr. Benjamin Esterman; treasurer, Dr. Leon Ehrlich.

At its annual meeting on May 28, 1946, the Milwaukee Oto-Ophthalmic Society elected the following officers: president, Dr. Meyer Fox; vice-president, Dr. Frank G. Treskow; secretary-treasurer, Dr. Earl W. Mertens; directors, Drs. Ralph T. Rank, Thomas McCormick, and Herbert Schmidt.

The Reading Eye, Ear, Nose, and Throat Society has distributed its War Fund, both principle and interest, as outright gifts to its members who were in the Armed Forces. Each one was given \$644.

PERSONALS

Dr. Lawrence T. Post, professor and head of the department of ophthalmology, Washington University School of Medicine, St. Louis, delivered the Edward Jackson Memorial Lecture on April 19th at the University of Colorado School of Medicine, Denver, under the auspices of the Medical Society of the City and County of Denver. His subject was "Changing eyes in a changing world."

At the meeting of the Western Association of Industrial Physicians and Surgeons on June 30th, in San Francisco, Dr. Hedwig S. Kuhn of Hammond, Indiana, presented a paper on "Right eyes for the job."

Dr. David F. Gillette, professor of ophthalmology of Syracuse University College of Medicine, became professor emeritus on July 1st. Dr. Harold H. Joy has been appointed professor of ophthalmology to succeed him.

At a special session of the Minnesota Academy of Ophthalmology and Otolaryngology, at the 93d annual session of the Minnesota State Medical Association in St. Paul, on May 20th, Dr. Elmer A. Vorisek presented a paper on "Evaluation of the newer therapeutic agents in ophthalmology." This paper has been accepted for publication in the Journal.

RAMNAY, ROBERT &

MUSTARD-GAS BURNS OF HUMAN EYES IN WORLD WAR II*

GEORGE I. UHDE, M.D.†

Portland, Oregon

Although chemical warfare was not used during World War II, useful information about chemical eye injuries nevertheless accumulated, mostly from experimental work but also from unfortunate factory, transportation, and training accidents.

The information presented herein was obtained from personal observation of casualties treated at Edgewood Arsenal over a period of two years and of casualties resulting from experimental, factory, training, and transportation accidents in the European Theater Operations during a subsequent period of 27 months.

Of 1,097 eye, ear, nose, and throat patients treated at Edgewood Arsenal during the 17 months preceding March 1, 1943, 1,008, or 91 percent, were due to mustard vapor. Of this latter number, 790, or 78 percent, had eye burns.

Only 80 out of 1,097 patients, or 7

percent, knew definitely their time of exposure. These 80 knew because of accidents, such as a sudden break in the shell-filling line releasing large quantities of mustard vapor which was detected by the sense of smell. In these 80 patients, the shortest interval between exposure and onset of symptoms was 2 hours, the longest 24 hours, with a mean of about 8 hours. The remaining 1,017, or around 93 percent, were due to exposure to slow leaks which were usually not detected by smell but, when detected, the sense of smell soon became dulled so that the workers were unaware of their danger.

CLASSIFICATION OF EYE BURNS

The following classification proved of practical value in the treatment and prognosis of casualties in fixed installations. It is believed this classification would be equally useful to medical officers in forward echelons where the problem is not so much a question of treatment and prognosis but simply as to whether a soldier is a casualty and should be evacuated for ophthalmic care.

GROUP 1: MILD CASES

- a. Symptoms: Gritty, foreign-body sensation; may have very slight lacrimation, but no true photophobia.
- b. Lids: May be slightly swollen, usually not.
- c. Conjunctival discharge: May have slight lacrimation.

* Presented as part of a lecture to classes attending the Medical Field Service School, American School Center, European Theater Operations, United States Army.

† Formerly Chief, E.E.N.T. Service Station Hospital, Chemical Warfare Center, U. S. Army, Edgewood Arsenal, Maryland, and Experimental Officer in Ophthalmology, Chemical Defence Experimental Station, Porton, England [Lt. Col. (MC) A.U.S.].

The author takes this opportunity to express his appreciation to Mr. R. Foster Moore, F.R.C.S., Comdr. E. B. Dunphy (MC) U.S.N.R., Prof. Ida Mann, Col. Derrick Vail, A.U.S., and Surgeon Capt. A. Fairley, R.N., for their kind and invaluable assistance on numerous occasions.

Fig. 1 (Uhde). Group I: Mild mustard-vapor burn, showing injection of only those conjunctival vessels normally exposed between the lids.

- d. Conjunctiva: Congestion of only the conjunctiva normally exposed between the lids (see fig. 1).
- e. Cornea: Clear, does not stain with fluorescein.
- f. Recovery: Spontaneous within five to seven days.
- g. Treatment: Not required, do not use a mydriatic.
- h. Duty: Full duty, do not evacuate.

GROUP II: MODERATE CASES

- a. Symptoms: Gritty, foreign-body sensation and may have slight lacrimation, photophobia, and blepharospasm.
- b. Lids: Slight to moderate swelling, able to open eyes.
- c. Conjunctival discharge: Slight to moderate lacrimation; may have slight mucopurulent discharge.
- d. Conjunctiva: Congestion of the whole conjunctiva, even that normally protected by the lids (see fig. 2).
- e. Cornea: Clear, but may have punctate staining with fluorescein.
- f. Recovery: Usually spontaneous within 7 to 14 days.
- g. Treatment: If cornea stains with fluorescein, dilate pupil with homatropine (in Negroes use atropine).
- h. Duty: Full duty if tactical situation

is bad, evacuate later; if tactical situation is good, evacuate after mydriasis is completed.

GROUP III: SEVERE CASES

- a. Symptoms: Severe, gritty, foreign-body sensation, ocular pain, lacrimation, photophobia, blepharospasm, blurred vision, and headache.
- b. Lids: Severe swelling, unable to open eyes voluntarily. Lids can be separated only a few millimeters (see figs. 3, 4, and 5).
- c. Conjunctival discharge: Severe lacrimation with slight to very severe mucopurulent discharge.
- d. Conjunctiva: Severe congestion, thromboses, hemorrhages, vessel variation in caliber and necrotic patches (stains yellow with fluorescein).
- e. Cornea: Gray, hazy, irregular, roughened ("orange peel"), band staining with fluorescein. Hypoesthesia.
- f. Recovery: Delayed at least weeks; may be subject to relapses with corneal vascularization; requires ophthalmic observation for months and perhaps years.
- g. Treatment: Atropine sulfate (1 percent), penicillin. Evacuate.

Fig. 2 (Uhde). Group II: Moderate mustard-vapor burn, showing injection of all conjunctival vessels, even those normally protected by the lids.

CLINICAL COURSE

The clinical course of a mustard-gas burn of the eye can perhaps be best shown by a case report illustrating each group in the foregoing classification.

GROUP I: MILD-CASE REPORT

A white woman, aged 22 years, was engaged from 3 p.m. to 5:30 p.m. in washing out bottles which had contained mustard. About 12:30 a.m. (eight hours after exposure) she was awakened with irritation, gritty foreign-body sensation, of both eyes.

Examination, 24 hours after exposure, showed slight reddening of the lid margins, injection of those conjunctival vessels normally exposed between the lids (fig. 1), and corneal epithelial flecks (best seen by slitlamp retroillumination and probably due to edematous swelling of individual epithelial cells). It is believed by some observers that these flecks are pathognomonic of exposure to mustard vapor.

The patient was asymptomatic four days after exposure, and the conjunctival injection and epithelial flecks disappeared three days later.

GROUP II: MODERATE-CASE REPORT

A white woman, aged 18 years, after

working for two days counting mustard-droplet-contaminated cards under a ventilator, developed grittiness, lacrimation, photophobia, and blepharospasm and was in considerable discomfort. She was wearing eyeshields. On awakening in the morning, she had difficulty in opening her eyes.

Examination, 36 hours after exposure, showed moderate swelling of the lids (fig. 2), difficulty in keeping her eyes open in bright light (photophobia), injection of all conjunctival vessels even those normally protected by the lids, and bedewing, but no staining, of the epithelium over the lower halves of the corneas.

The pupils were dilated and within three days the patient was comfortable. All signs disappeared by the 14th day.

GROUP III: SEVERE-CASE REPORT

A senior officer, aged 44 years, standing about two yards from two land mines (94 lbs. of mustard) which inadvertently detonated, felt a "watery-like," painless splash across his face and in both eyes. Both eyes were irrigated with normal saline about three minutes later but for only a few seconds. Ten minutes after the accident, his eyes were again irrigated with normal saline but again for only a few seconds.

Although his lids were swelling meanwhile, his first disturbing symptoms about the eyes appeared seven hours after the accident. They were lid edema, which was so severe that he was unable to open his eyes voluntarily, and lachrimation. Pain was present only when the lids were separated and the eyes exposed to light; this always caused profuse lachrimation,

Fig. 3 (Uhde). Group III: Severe mustard burn, showing profuse mucopurulent discharge and swelling of lids seven days after the eye was splashed with mustard.

severe pain, photophobia, and blepharospasm.

Twenty-four hours after the accident his eyelids were "stuck together" and could be separated only after irrigation with normal saline. Symptoms and signs remained unchanged.

Because of the severe skin burns, it was impossible to make a satisfactory slitlamp examination until the seventh day, at which time the following findings were observed: The lids were so swollen that it was almost impossible to examine the corneas. A slight mucopurulent discharge oozed between the lids of the right eye and a profuse discharge from the left eye (fig. 3). The bulbar conjunctival vessels varied considerably in caliber; that is some were so constricted and irregular that they could barely be seen with the slitlamp; others were engorged, with localized areas of laking of the blood

stream; these conditions were especially marked in the vessels normally exposed in the interpalpebral space. There was either a stagnation of the blood current or a thrombosis in these constricted vessels. The edema of the interpalpebral conjunctiva together with the constricted and thrombosed blood vessels with resultant necrotic patches produced a marbling effect. Conjunctival and subconjunctival hemorrhages were numerous. Some of the groups of limbus vessels were constricted, whereas others were congested; but not nearly to the extent seen in the superficial conjunctival vessels. The ciliary vessels were injected, especially those of the left eye. A band of bright green from fluorescein staining extended across both corneas, limited to the areas normally exposed in the interpalpebral fissures. The remaining corneal surfaces, however, stained a lighter and duller shade of green, indicating that the entire epithelial surfaces were damaged. The corneal reflex of the left eye was very irregular, because the surface was roughened and pitted (orange-peel or *peau d'orange*).

With the slitlamp, it was found the edema and infiltrates extended into the anterior third of the corneal stroma of the right eye and throughout all layers of the cornea of the left eye even including the endothelium. Correspondingly, the epithelium, Bowman's membrane, and the anterior third of the substantia propria of the right eye stained, while in the cornea of the other eye the stain extended down to and included part of the endothelium. The green stain did not appear to extend into the aqueous, although, because of the intense edema of the intervening corneal tissue, it was difficult to be sure of this or of the condition of the iris of the left eye.

The only obvious change during the second week was a gradual diminution of the mucopurulent discharge.

The patient was not able to open his

eyes until the third week. At this time, the conjunctival discharge was minimal. Although there was neither pain nor headache, there were complaints of blurred vision, lacrimation, photophobia, and blepharospasm of both eyes. Corneal sensation was diminished in both eyes, as it had been all along. The conjunctival vessels appeared unchanged. There were remains of conjunctival and subconjunctival hemorrhages in the right eye, and fresh hemorrhages appeared in the left. The newly regenerated corneal epithelium showed innumerable flecks and some hydrops, in contrast to the previous mass edema and bedewing.

During the fourth week the edema and congestion of the lids of the right eye improved considerably. Conjunctival congestion was minimal. Some of the superficial epithelial cells, however, showed flecks and hydrops. There was very little improvement in the left eye (figs. 4 and 5), compared with the results of the examination during the previous week.

There was gradual improvement but there were no significant changes during the fifth week.

On the fortieth day there was an early superficial vascularization of the cornea of

Fig. 4 (Uhde). Group III: Severe mustard burn of left eye 24 days after being splashed with mustard, showing profuse tearing and swelling of the lids even in the dark (monochrome reproduction from color transparency taken at one-seventy-fifth second in the dark. The camera lens was focused by dim flashlight).

Fig. 5 (Uhde). Group III: Severe mustard burn 24 days after the eye was splashed with mustard, showing lids involuntarily separated, engorged conjunctival and limbal vessels beneath the lids, and necrotic conjunctiva, with thromboses and hemorrhages beneath the interpalpebral space.

the left eye at the 8-o'clock position, as shown by the sprouting off of new capillaries from the limbal loops. This vascular invasion was preceded by a broad area of secondary edema and small hemorrhages but by no blood islets, at this time.

Infiltrates and edema were stratified in layers between the lamellae throughout the remaining corneal tissue. The superficial cells of the cornea of the right eye still showed flecks and an occasional hydropic cell. New blood vessels were found in the necrotic conjunctiva of both eyes.

On the fiftieth day this patient was transferred to the service of Prof. Ida Mann, The Eye Hospital, Oxford University. He will most likely require observation and treatment for many years.

COMPARISON OF THE CLINICOPATHOLOGIC FINDINGS IN CASUALTY AND NON-CASUALTY PATIENTS

The following findings are those observed in six eyes splashed with liquid mustard, and insufficiently irrigated with normal saline, and six eyes exposed to mustard vapor during a training accident. The splashed eyes were true battle cas-

ualties in the sense that the men were thereafter unable to fight; the vapor-exposed eyes were noncasualties. In none was there any pain whatsoever when the eyes were splashed, confirming the experience of those similarly injured in World War I. The mustard droplets felt like "watery" painless fluid. All the patients with splashed eyes complained of a severe, gritty, foreign-body sensation and of severe lacrimation, photophobia, blepharospasm, and blurred vision 3 to 24 hours after exposure. Two of these patients complained of headache; there were no signs of iritis.

One of the patients with vapor-burned eyes complained of a gritty, foreign-body sensation and two complained of gritty, foreign-body sensation and lacrimation about seven hours after exposure. One patient complained of mild photophobia. Three patients, although asymptomatic, had signs of a vapor burn.

TABLE 1

COMPARISON OF SYMPTOMS IN SIX CASUALTY
AND SIX NONCASUALTY MUSTARD-
EXPOSED EYES

Symptoms	Casualty		Non-casualty*	
	No.	Per-cent	No.	Per-cent
Pain immediate	0	0	0	0
Pain late	6	100	0	0
Gritty feeling	6	100	3	50
Lacrimation	6	100	2	33
Photophobia	6	100	1	16
Blepharospasm	6	100	0	0
Blurred vision	6	100	0	0
Headache	2	33	0	0

* May be asymptomatic but with conjunctival injection and/or corneal epithelial flecks.

Whereas the lids of the eyes contaminated with liquid mustard were so severely swollen (even as early as four hours after exposure) that the casualties were unable to open their eyes for days and had severe blepharospasm, the lids of the eyes exposed to vapor only were never more than moderately swollen and

without blepharospasm. It is believed, therefore, that severe swelling of the lids (except for that due solely to external lid burns) should be considered a sufficient criterion for evacuation.

TABLE 2

COMPARISON OF THE LID SIGNS IN SIX
CASUALTY AND SIX NONCASUALTY
MUSTARD-EXPOSED EYES

Lid Signs	Casualty		Non-casualty	
	No.	Per-cent	No.	Per-cent
Severe swelling (unable to open eyes)	6	100	0	0
Moderate swelling			3	50
Slight swelling			1	16
No swelling			2	33
Blepharospasm	6	100	0	0

Mucopurulent conjunctivitis developed in four of six eyes splashed with mustard, being very severe in one instance. This is in marked contrast to the findings in vapor-exposed but noncasualty cases.

TABLE 3

COMPARISON OF CONJUNCTIVAL DISCHARGE IN
SIX CASUALTY AND SIX NONCASUALTY
MUSTARD-EXPOSED EYES

Conjunctival Discharge	Casualty		Non-casualty	
	No.	Per-cent	No.	Per-cent
Lacrimation	6	100	3	50
Mucopurulent, severe	1	16	0	0
Mucopurulent, moderate	1	16	0	0
Mucopurulent, slight	2	33	1	16

The conjunctival changes observed in the splashed eyes were: severe congestion, thromboses of vessels, hemorrhages, necrotic patches with budding new vessels, and marbling. Similar, but much slighter, changes were found in the limbus.

Four of six vapor-exposed eyes showed conjunctival congestion. The other two eyes had epithelial flecks. It is felt, therefore, that epithelial flecks have about the

same diagnostic and prognostic significance as has conjunctival congestion. Except for congestion and epithelial flecks, the vapor-burned eyes appeared normal.

Four of six splashed eyes showed bandstaining, punctate staining, bedewing, and epithelial flecks of the corneas. The other two eyes would probably have shown the same changes, but the patients were too ill for slitlamp examination. Five of these eyes had hazy, gray (opaque), irregular, faceted corneal surfaces (orange-peel or peau d'orange).

TABLE 4

COMPARISON OF CONJUNCTIVAL SIGNS IN SIX CASUALTY AND SIX NONCASUALTY MUSTARD-EXPOSED EYES

Conjunctival Signs	Casualty		Non-casualty	
	No.	Per-cent	No.	Per-cent
Congestion	6	100	4*	66
Thromboses	6	100	0	0
Hemorrhages	4	66	0	0
Vessel variation in caliber	6	100	0	0
New vessels	5†	83	0	0
Necrotic patches	6	100	0	0
Marbling	6	100	0	0

* Two patients had only epithelial flecks.

† One patient died too early for new-vessel formation.

Five of six vapor-exposed eyes showed epithelial flecks (one patient was too ill with skin burns for slitlamp examination). There was punctate staining of the epithelial cells in two cases and epithelial bedewing in another.

Five of six splashed eyes had edema of the anterior part of the substantia propria (two patients were too ill for slitlamp examination, but one eye was examined histologically). Other stromal changes in this group were: complete edema, cellular infiltration, stratification, and fibrous scarring. One of these patients had definite corneal vascularization on the fortieth day.

The substantia propria of the vapor-burned eyes appeared normal.

TABLE 5

COMPARISON OF CORNEAL-SURFACE CHANGES IN SIX CASUALTY AND SIX NONCASUALTY MUSTARD-EXPOSED EYES

Corneal-Surface Signs	Casualty		Non-casualty	
	No.	Per-cent	No.	Per-cent
Epithelial flecks	4†	66	5††	83
Band staining	4	66	0	0
Punctate staining	4†	66	2	33
Bedewing	4	66	1	16
Hypoesthesia	6	100	0	0

† Two patients, too ill for slitlamp examination.

†† One patient, too ill for examination (slitlamp).

Only one eye showed edema of the endothelium; the endothelial cells stained with fluorescein; the aqueous appeared normal.

One patient died 28 hours after exposure to mustard droplets from pseudodiphtheric inflammation of the respiratory passages and bronchopneumonia with respiratory obstruction and cardiac failure. He was a senior officer, aged 47 years, standing over two chemical land mines containing 94 lbs. of mustard which unexpectedly detonated. He was drenched with liquid mustard. Although he felt fluid enter both eyes, he had no sensation of pain but did have an immediate, sandy or gritty foreign-body

feeling, which persisted thereafter. Irrigation with normal saline was started at the end of about three minutes but was very brief.

The patient complained of blurred vision and of severe lacrimation, photo-

Fig. 6 (Uhde). Group III: Photomicrograph of a tangential section of the cornea of a mustard-splashed eye, showing destruction of epithelium, wrinkling of Bowman's membrane, swelling of the lamellae, and infiltration of leukocytes ($\times 200$)

phobia, blepharospasm, and, of a gritty, foreign-body sensation. He was especially troubled about his blurred vision: he was unable to identify his surroundings, his friends, physicians, and nurses.

Upon examination, five hours after the accident, the upper and lower lids were so edematous and congested that they could be separated only about 3 mm. The tarsal and bulbar conjunctivas were severely chemotic and congested with numerous subconjunctival and conjunctival hemorrhages. Many of the bulbar conjunctival vessels were constricted and thrombosed while others were engorged, including those of the limbus. The ciliary

vessels were congested. The corneal surfaces appeared hazy, gray (opaque), with irregular faceted surfaces (orange-peel). A horizontal band of deep-green staining with fluorescein was observed, limited to that area of each cornea normally exposed in the interpalpebral space. The remaining corneal surfaces, normally protected by the lids, did not stain but appeared rough and opaque.

Twenty-four hours after the accident, or five hours before death, the whole corneal surfaces stained except for very small areas contiguous with the upper limbus. Even those areas, however, were rough and hazy in appearance. Corneal sensation was diminished.

At necropsy, the right eye was removed for histologic examination. The eye was fixed in 10-percent formol-saline, washed in running water for 24 hours, and placed in Zenker's solution. After dehydration and embedding in paraffin, tangential sections were cut and stained with Ehrlich's hematoxylin-eosin and Van Gieson's stains.

Examination of the histologic sections showed complete destruction of the corneal epithelium (fig. 6). Bowman's membrane was wrinkled, swollen, and stained very poorly. The spaces between the lamellae were distended with fluid and leukocytes. Most of the endothelial cells were detached from Descemet's membrane.

PIGMENTATION

It was observed in a few Negroes treated at Edgewood Arsenal that brown pigment invaded the superficial corneal cells after damage from mustard. This was a common observation in mustard-burned rabbits' eyes as first reported by Ida Mann.

PROTECTION

Gas masks gave complete protection to the eyes and lungs.

Eyeshields protected the eyes against drops but were not relied upon to give protection against vapor (group II: moderate case report), although in some instances (table 7) the eyeshields appeared to give some protection even against vapor. That the ordinary antigas eyeshields

EVACUATION OF EYE CASUALTIES

Since eyeshields cannot be depended upon to give protection against vapor, gas masks were worn by those attending contaminated cases. During this war, after a large transportation accident, over 100 vapor eye casualties resulted from ex-

gave protection against mustard droplets was shown by the following training accident. Two bombs, which the instructor thought contained simulated mustard but actually contained mustard, were detonated 15 to 20 yards upwind of a gun crew in a gun pit. All the soldiers, except one wearing ordinary spectacles, wore eyeshields. Many of the soldiers stated that the eyeshields were splashed. Not one of the soldiers wearing eyeshields developed symptoms or signs of mustard-gas burns (patients 5, 16 and 8 to 11 incl). The soldier wearing spectacles had the most severe symptoms and lesions with bedewing and edema extending into the substantia propria.

posure to mustard-contaminated patients because gas masks were not worn.

GAS-MASK SPECTACLES

The ordinary spectacle frame cannot be worn in conjunction with the ordinary gas mask. The overall width of the spectacle frame is too great. The gas mask rests on the frame and presses the nasal bridgepiece heavily onto the nose. Moreover, there is leakage of gas around the temple-pieces.

Early in World War II an attempt was made to overcome these difficulties by projecting the temple-pieces directly backward off the metal rims of the lenses, thereby reducing the overall width of the

spectacle frame and, at the same time, permitting the temple-piece to fit more closely to the skin of the face. Such a spectacle was unsuccessful, largely because the frame required accurate adjustment initially and frequent readjustment in the field, which involved a tremendous amount of work and was never done. If the frame is not adjusted properly, leakage of gas invariably occurs around the temple-pieces, and the results in battle could be quite disastrous. Nevertheless, a very successful and ingenious means was finally found for the insertion of a spectacle lens directly behind the gas-mask lens.

TRAINING

Although the vast majority of ophthalmic chemical casualties were vapor burns, and as physicians we are very much interested in this important fact, I cannot concur with the belief of some observers that splash injuries of the eye were over-emphasized in training. It is true the eye is a small target, but it is also true that the soldier is unable to do much about vapor burns, whereas his recovery from a

liquid contamination depends upon whether he himself irrigates his eye or instills an ointment, and his action at that particular moment will usually reflect upon his training. Finally, although a soldier has eyeshields, if he doesn't wear them and he is blinded from a splash, the Service is nonetheless responsible.

CONCLUSIONS

Mustard vapor was responsible for the great majority of chemical eye casualties seen by ophthalmologists during World War II, as shown by the fact that of 1,097 eye, ear, nose, and throat burns treated at Edgewood Arsenal over a period of 17 months, mustard vapor accounted for 1,008, and of this number 790 were eye burns.

A classification of mustard eye burns with case illustrations is presented. This classification proved of practical value in the treatment and prognosis of casualties in fixed installations and may be useful to medical officers in forward echelons.

The clinicopathologic findings in casualty and noncasualty patients are discussed.

EARLY OCULAR MANIFESTATIONS IN THE LAURENCE-MOON-BIEDL SYNDROME*

DONALD J. LYLE, M.D.
Cincinnati, Ohio

The Laurence-Moon-Biedl syndrome, consisting of obesity, hypogenitalism, mental retardation, polydactyly, and retinal degeneration, is occasionally seen by the ophthalmologist when a child is presented complaining of loss of sight which is not helped by correction of the refractive error.

Laurence and Moon⁸ in 1866 described four cases of retinitis pigmentosa with developmental disturbances occurring in the same family. These children all had night blindness and no apparent constriction of visual fields. Höring,⁶ Stör,¹⁸ and DeWecker²¹ at about the same time noticed similar patients with polydactyly. Fröhlich⁵ in 1901 described the type of obesity, bearing his name, which is also found in these cases. Biedl² in 1922 correlated these symptoms; adding mental deficiency, and presented two additional cases.

Obesity of the Fröhlich (pituitary) type shows a fat distribution similar to that in the female. Hypogenitalism is not invariably constant. Mental retardation may be slightly evident in the early stages but usually increases along with the progression of the other symptoms. Polydactyly is of the postaxial type. There is never more than one extra digit. Syndactyly is also found.¹³ There appear to be two types of retinal dystrophy (a term implying degeneration of abiotrophic nature). One shows a resemblance to typical retinitis pigmentosa, the other has the appearance of cerebromacular degeneration. Nystagmus and strabismus have oc-

asionally been mentioned in reports of these cases. One or more of the symptoms of the syndrome may be absent.¹⁹

Of the symptoms comprising the syndrome, polydactyly is an hereditary mesoblastic fault or maldevelopment; the remainder are ectoblastic of probable abiotrophic nature, as there is progressive degeneration of previously fully developed and functioning tissue. The seat of the neuro-ectodermal disturbances is in the prosencephalon (forebrain) from which the optic vesicle develops to form the nervous and pigmentary layers of the retina. The prosencephalon consists of the telencephalon (the cerebral hemispheres) and the diencephalon (the thalamic region). These produce the optic hypothalamus of the former mammillary hypothalamus of the latter. The optic hypothalamus is apparently the location for the cerebral disturbance producing the syndrome. It consists of the lamina terminalis (anterior wall of the third ventricle), the optic chiasm and optic tracts and the tuber cinereum, infundibulum, and hypophysis. This anatomic association indicates the close relationship between the retinal and cerebral structures and suggests the reason for the combination of symptoms producing the syndrome as the result of regional degeneration. Whether this failure of viability is primarily ectoblastic or mesoblastic (a result of nutritional decline) is of speculative interest as pathologic examination of the few autopsies reported has, so far, failed to demonstrate substantial evidence on behalf of either primordial tissue. This falls in line with the discussion as to the primary causative agent, or the primary

* Presented at the 81st annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, November, 1945.

tissue, involved in the degeneration found in retinitis pigmentosa.

The subjective symptom of the Laurence-Moon-Biedl syndrome is loss of central vision not correctable with glasses. There is an early reduction of central vision; later peripheral constriction. Early visual-field studies show an expanding central scotoma; peripheral concentric constriction gradually develops. The para- and pericentral fields remain until last.

Ophthalmoscopic examination may reveal nothing abnormal at first. White or pigmented macular spots or stippling appear usually in the early stage. Later the periphery of the retina begins to show atrophy, and finally pigment appears. With the peripheral changes, the retinal blood vessels become attenuated, and pallor is seen at the disc.

The onset of the Laurence-Moon-Biedl syndrome is in early life and may be detected before the school age. Prognosis is grave, for there is gradual reduction of mentality and loss of sight. Associated conditions have previously been mentioned as the other symptoms of the syndrome.

Family history is generally negative, although some authors report frequent alcoholism and mental instability in the ancestry. Consanguinity is variously noted as being between 14 percent (first cousins) and 23 percent (first and second cousins). The condition is recessive and apparently consists of a combination of mesoblastic skeletal deformity and epiblastic retinal and cerebral dystrophy, probably due to a mutation of two genes in the same chromosome.

CASE REPORTS

Case 1. F. R., aged 20 years, is the third of three children. An older brother and sister are normal. Her weight was 148 pounds and height 65 inches. The

sixth finger on the right hand was removed nine years ago. Menstruation has been regular since the age of 15. Diabetes insipidus is present. Mental retardation is not evident to any great extent.

This young lady came for an eye examination because of failing vision. She thought her sight began to disturb her at about 10 years of age. At the time of the examination, vision in the right eye was 20/200, in the left eye 20/200. Refractive correction did not improve vision. A small (5-degree), absolute central scotoma was found in both visual fields. Peripheral fields were normal. Ophthalmoscopic examination showed some retinal atrophy (fig. 1), with pallor of the discs and slight attenuation of the retinal vessels. This fundus picture was believed to be an early stage in the course of pigmentary degeneration of the retina, the prepigmentary stage. With polydactyly and these eye findings, the impression is that of an incomplete Laurence-Moon-Biedl syndrome.

Case 2. M. J. D., aged 12 years. There is one older child who is well. Her weight was 138 pounds and height 59 inches. Menstruation has not yet appeared. The child is obese. She was very thin at birth but became obese from six weeks on. She had thyroid and pituitary treatment for two years without benefit. She has an enormous appetite. Reducing diet was prescribed but not followed. There is no history of polyuria or polydipsia. Urine examination was negative. Basal metabolic rate was minus-8 percent. Kahn test was negative. A sixth finger on the right hand was removed. Skull plates were negative, ossification corresponding to age. On the Stanford-Binet test, a mental age of seven years, three months and an I.Q. of 60 were obtained. This classifies the child as definitely feeble-minded and in the group of "moron." The child is in the

Fig. 1 (Lyle). Early stage of Laurence-Moon-Biedl syndrome. Retinal atrophy with absolute central scotomas.

fifth grade of school but will have to repeat. The mother thinks she has good memorizing ability but poor reasoning.

The child was brought for eye examination because of poor vision which, ap-

parently, glasses could not correct. Mental retardation was acknowledged by the mother, who thought that it was due to the poor sight. At the time of the examination, vision in the right eye was 20/200,

in the left eye 20/200. Refractive correction with a compound myopic astigmatic lens for each eye improved vision to 20/100 in the right eye and 20/70 in the left. A small (5-degree), absolute central scotoma was found in both visual fields. Peripheral fields showed some temporal constriction. Ophthalmoscopic ex-

dactly, and retinal degeneration, a diagnosis of Laurence-Moon-Biedl syndrome was made.

Case 3, A. P., a woman aged 36 years, was examined 18 years ago because of poor vision. At that time she had stopped going to school where she was not pro-

Fig. 2 (Lyle). Early stage of Laurence-Moon-Biedl syndrome. Retinal atrophy with absolute central scotomās.

amination revealed some retinal atrophy (fig. 2), with pallor of the discs and slight attenuation of the retinal vessels. The atrophy is somewhat more pronounced than in the preceding case (see figure 1). Pigmentation of the periphery of the retina has not yet appeared.

With the presence of obesity, possible hypogonadism, mental retardation, poly-

gressing and had gone to work, but her vision was so bad she could not hold her job. Her low intelligence, which was quite evident upon examination, was not at first accepted by the mother, who blamed reduced vision entirely for the girl's lack of progress.

The exact weight and height were not taken. However, the patient was short in

Fig. 3 (Lyle). Advanced stage of Laurence-Moon-Biedl syndrome. Plaques of retinal degeneration in macular area. Peripheral atrophy with pigmentation. Constricted visual fields with central scotomas.

height and quite obese. She had never menstruated. The basal metabolic rate was minus-28 percent. Urine examination was negative. The blood Wassermann test

was negative. The skull plates were negative. A sixth finger on the left hand had been removed. An I.Q. of less than 60 was obtained.

When first seen, vision in the right eye was 10/200, in the left eye 8/200. There was a small, round, absolute central scotoma of about 5 degrees in each eye. Peripheral fields were normal. A myopic correction improved vision in each eye to

peared, mental retardation was possibly more marked, and retinal degeneration with loss of vision had greatly increased.

At the last examination, the right eye had only light perception, the left 1/200. Ophthalmoscopic examination showed

TABLE 1
SYMPTOMS OF THOSE CONDITIONS FROM WHICH LAURENCE-MOON-BIEDL SYNDROME SHOULD BE DIFFERENTIATED

	Heredo-macular Degeneration	Leber's Hereditary Optic Atrophy	Cerebro-macular Degeneration	Laurence-Moon-Biedl Syndrome	Retinitis Pigmentosa
Onset	Periods of physiologic change	Indefinite, second decade	Childhood, second dentition	Early childhood	Puberty or early adult
Inheritance	Recessive—irregular Dominant	Recessive and sex-linked in males through females	Recessive	Recessive	Recessive, Dominant, Sex-linked
Sex	About equal	Males predominate	About equal	About equal	Males predominate
Chief symptoms	Diminution of vision	Diminution of vision	Diminution of vision	Diminution of vision	Night blind constricted v.
Central visual fields	Scotoma	Scotoma	Scotoma	Scotoma	Normal until late
Peripheral visual fields	Normal	Constriction slight & late	Constriction to blindness	Constriction to blindness	Ring scotoma expanding
Central fundus	White & pigment stippling	Nothing characteristic	White & pigment stippling	White & pigment stippling	Pigment stippling
Peripheral fundus	Normal	Nothing characteristic Atrophy	Marked atrophy Pigment late	Atrophy Pigment late	Early pigment and atrophy
Peripheral fundus	Normal	Nothing characteristic Atrophy	Marked atrophy Pigment late	Atrophy Pigment late	Early pigment and atrophy
Papilla	Normal or pale	Pallor, more temporal*	Gradual pallor to atrophy	Gradual pallor to atrophy	Gradual pallor
Retinal vessels	Normal	No changes constant	Gradual attenuation	Gradual attenuation	Gradual attenuation
Termination	Central vision impaired or lost	May recover some vision	Blindness & early death	Blindness & dementia	Blindness late
Affiliated conditions	Nothing constant	None	Marked cerebral degeneration	Obesity Hypogenitalism Mental reduction Polydactyly	Deafness in recessive type

* Early normal discs or papilledema; later atrophy of papillo-macular bundle; may resemble either primary or secondary atrophy.

20/200. Ophthalmoscopic examination revealed some white macular and paramacular stippling, with some pallor of the discs and slight attenuation of the retinal vessels.

When last examined, 12 years after the first examination, all of the symptoms had increased. The obesity was more evident, the weight was 165 pounds, and the height 62 inches. Menstruation had never ap-

large plaques of central retinal degeneration, atrophic discs, and attenuated retinal vessels (fig. 3). Peripheral retinal degeneration was marked with pigment deposits. Visual fields showed nearly a meeting of the greatly constricted peripheral fields with the original, central scotomata.

With obesity, hypogenitalism, mental retardation, polydactyly, and retinal degeneration this patient has been diagnosed

as having a Laurence-Moon-Biedl syndrome.

Laurence-Moon-Biedl syndrome must be differentiated from Leber's hereditary optic atrophy, which it resembles in its early stage, and from typical retinitis pigmentosa, which it resembles in its advanced stage. It must be differentiated from the various types of cerebro-macular degeneration which may have very similar subjective symptoms and fundus appearance. However, cerebral degeneration is much more manifest in cerebro-macular degenerative conditions than it is in the Laurence-Moon-Biedl syndrome (table 1).

CONCLUSION

The Laurence-Moon-Biedl syndrome shows, at first, nonpigmented retinal degeneration with loss of central vision, with a small, central scotoma. The macular area may show some white or pig-

mented stippling. The retinal vessels and disc appear normal.

As the retinal degeneration proceeds, pigmentation appears in the periphery, the retinal vessels become more and more attenuated, and the disc increases in pallor. The macular area shows increased degenerative changes, with or without pigmentation.

The resemblance to Leber's hereditary optic atrophy and the various types of cerebro-macular degeneration with central scotomas, loss of vision, and cerebral symptoms is remarkable in the early stages of both conditions. In later stages, the pigmentary degeneration may be confused with typical retinitis (retinosis) pigmentosa by the casual observer who fails to take a detailed history of the case and to make a complete examination in order to reveal the other components of the syndrome.

PLASTIC EYE IMPLANT*

A. D. RUEDEMANN, M.D.
Cleveland, Ohio

The patient's appearance after enucleation has long been a problem for the eye surgeon. Only patients with deep-set eyes and narrow fissures actually wear a prosthesis without "stare" or a sunken-in appearance. The socket cannot be filled out by a loose fitting "reform," "stump," or other type of shell eye, because of constant shrinkage of other orbital tissues as well as the ocular conjunctiva. Sub-

capsule. The shell eye uses the entire area, wall to wall, and there is no place for the prosthesis to move. Implants within the muscle cone or inside the scleral shell, if fitted with a "stump" shell, give good movement. However, these implants also "stare" on lateral gaze and actually do not move very extensively.

With the advent of the new plastic reform eye, I thought that it might be

Fig. 1 (Ruedemann). Plastic implant showing position of holes for sutures and paddles.

sequently, smaller shells must be fitted when actually the area to be filled is larger. Attempts to fill out the socket by plastic addition above will eventually result in a pushing out below with loss of the lower cul-de-sac from pressure of the upper lid and weight of the prosthesis.

Normally the orbit is completely occupied, the eyeball using one fifth of this total area. Therefore, loss of volume alone is sufficient to produce an enophthalmic appearance unless this volume is replaced. "Stare" is present only when the eyeball does not rotate within Tenon's

possible to use the material as a full eye implant. Mr. Fritz Jardon, then of the Mono Plastic Eye Company, now with the American Optical Company, made up, and I used, various sized and shaped eyes. Most of the early eyes were too small and wrongly shaped. Figure 1 shows the present type. Various types of suture material were tried, mostly unsuccessfully. The present method was developed by trial and error plus much effort. Failures were mostly mechanical, and until recently the problem seemed almost hopeless. Mr. Valentine Seitz, deceased, chief of the Electro-mechanical Engineering Division, aided materially in the designing of the eye and the method of attaching the muscles.

Tantalum wire (.005) was the only

*From the Cleveland Clinic. Read at the eighty-first annual meeting of the American Ophthalmological Society, at Hot Spring, Virginia, November, 1945.

suture material to hold up indefinitely (fig. 2). The wire is inert and does not cause tissue reaction. However, it is diffi-

cessfully placed, and none have been extruded with the present method of implantation. Only minor mechanical

Fig. 2 (Ruedemann). Double-armed tantalum suture.

cult to handle at first, breaks easily, and requires patience and care in handling. Granulation tissue does not tend to form except in cases of mechanical or surgical failure. Globes attached to muscles only with wire will stay in, but so much muscle is required in the suturing to maintain the attachment that the eye is set too deeply in the socket.

I believed that a firmer and more permanent attachment could be obtained by the use of an intermediate muscle plate of tantalum (fig. 3), the plate to be attached to the muscle and then to the plastic globe. Quite a number of different styles of plates were tried, and the present issue seems to be the most satisfactory to use and attach. This plate (fig. 2) is made of tantalum and sutured as in figure 3. It forms a solid unison with the muscle, and, with the paddle end placed in hole 3 and the two wire sutures passing through holes 1 and 2, the implant is firmly fixed (fig. 1).

To date over 100 eyes have been suc-

cessfully placed, and none have been extruded with the present method of implantation. Only minor mechanical

TECHNIQUE OF IMPLANTATION

Matching the good eye for color and outstanding iris markings may be accomplished in several ways. Color photography accurately reproduces markings

Fig. 3 (Ruedemann). Tantalum paddle attached to under side of muscle.

but not color. A matching set which is now being made available is likely to be more satisfactory. Except when executed

by experienced artists, such as our Miss Boyle, the eye may be more artistic than actual, and the color is not good. Eyes must be matched in daylight for accuracy in color.

Corneal size varies and must be measured. Most corneas measure 11 to 11.5 mm. in the horizontal meridian, and unless the vertical is much greater, the cornea may be round. Usually the 180-degree meridian is 0.5 mm. longer. The pupil also varies in size and must be carefully measured. The tendency is to make it too small, although it is rarely less than 3.5 mm. and averages 4.5 mm. The pupil is measured in daylight, not when facing sunlight or too bright a reflecting wall. The pupil may be off center, being closer to the nose, and can be duplicated as can any other outstanding characteristic. Mr. Jardon has been efficient in duplicating eye markings.

Former difficulty with color fading has been largely overcome. Occasionally an eye will fade because of the dyes or because the patient's body fluids work

Fig. 4 (Ruedemann). Circumcorneal incision.

through the slightly porous plastic material. To date, this has been a rare complication. Etching of the clear cornea is not a complication, nor is there a color change in the material itself.

A number of scleral colors should also be matched, for which there is now

a matching set. Individual scleral-vessel markings should be noted. Attention to these details results in the best appearance after operation.

It now requires 48 to 72 hours to process an eye. This time will be cut to 24 hours when the code method now being worked out is finally established.

Anesthesia. I have used both local and general anesthesia. Local anesthesia, accomplished by injecting 2-percent novo-

Fig. 5 (Ruedemann). Cutting of muscle with canaliculus knife.

caine deeply into the orbit in three places—inferiorly laterally, superiorly and inferiorly mesially—expedites the operation but is distressing for the patient. Sodium pentothal or avertin, according to the patient's age, is an easier anesthetic for the patient to bear. The bleeding is greater with general anesthesia than with local, and therefore there is more local reaction.

Operation. The operation requires about one hour, but varies with the speed of the operator. The procedure is simple enucleation with circumcorneal incision with scissors or canaliculus knife (fig. 4). *Dissect very little conjunctiva.* Button-hole Tenon's capsule alongside the superior rectus muscle, which should be picked up with the hook but not dissected too freely. Place muscle clamp and cut muscle with canaliculus knife (fig. 5). Fasten

muscle plate to underside of muscle with tantalum wire (fig. 3). This is mechanically difficult because the wire hardens and will break if kinked. To prevent kink-

Fig. 6 (Ruedemann). Paddles attached to the 4 rectus muscles.

ing it must be rolled on itself or kept straight. The sutures are 12 inches long. The Johnson and Johnson Company have promised a new tantalum-wire material, to which the needles will be swedged, and this wire will not break so easily. These two features would eliminate a major difficulty in the surgery; that is, breakage

Fig. 7 (Ruedemann). Paddle being inserted into plastic eye.

of the wire and tearing of tissues by the needle.

The best order in which to remove the muscles is as follows: Superior rectus, internal rectus, inferior rectus, and external rectus. The obliques are not attached unless the eye is prominent, then

they aid in keeping the eye forward. To date, I have attached the latter directly to the globe without the muscle plate. Most eyes have excellent movement without attachment of the obliques, and fastening these muscles is difficult. The loose ends of the double-armed sutures are held out of the way with hemostats. Care should be taken not to kink the wire.

After bleeding has been completely controlled, the implant is placed in the socket (fig. 6). Linen-thread loops have previously been placed in the attachment holes to aid in manipulating the implant (fig. 1). For each muscle three holes are placed at a prescribed distance from the limbus: internal rectus, 5 mm.; inferior rectus, 6 mm.; external rectus, 7 mm.;

Fig. 8 (Ruedemann). Method of attaching sutures.

superior rectus, 8 mm. I believe this may need to be revised, and we are now obtaining our own average distances.

The hole for the paddle tip is placed directly behind and between the attachment holes and is directed posteriorly. This allows the tip to be bent over and fixed. The superior rectus muscle with plate attached is picked up with a straight hemostat, and the tip is bent. The globe is depressed and the tip inserted into globe hole 3 (fig. 7). The wires are then passed through holes 1 and 2 and tied (fig. 8). Care must be taken not to break the wires, which should be held not too far away

from the knot in tying (fig. 9). The ends are twisted together and cut short and turned into hole 1 or 2 with a fine-tipped hemostat or watchmaker forceps. This should be carefully done, because a tip end penetrating the tissues becomes a sore point.

The internal, inferior, and external rectus muscles are sutured in order. Care in suturing and traction on muscles will prevent tearing of muscles. When obliques are used, they are fastened first by a weaving suture and then attached directly to the globe. A single interrupted suture through both the lateral and mesial conjunctiva covers the internal and external muscle and closes the conjunctiva (fig. 10).

When the patient has been operated upon previously for enucleation, the socket may again be opened. The conjunctiva is to be opened with a horizontal incision made with scissors. This cut must

Fig. 9 (Ruedemann). Tying of stitch.

be 10 mm. long. The conjunctiva is then dissected free all around, for 5 to 10 mm. Tenon's capsule is opened and split tulip-fashion for the four rectus-muscle slips. The posterior orbit is next opened to make room for the implant. A suture through each muscle slip aids in attaching the muscle plate. Care in placing this plate prevents subsequent squint. The conjunctiva is closed as in the previous procedure.

The implants may be varied in size and shape and can be made available for any type of restoration. I have used them in badly restored sockets with surprising results as to appearance and movement.

Fig. 10 (Ruedemann). Suturing of conjunctiva.

Very little attachment tissue is necessary, and by use of plates the eyes are retained in the socket. The ocular conjunctiva is not essential to the implant.

Dressing. A gauze pack, saturated with 5-percent sulfathiazole ointment, is placed under the lids. A pressure dressing is not desirable. Only loose-fitting gauze with an adhesive cover is necessary. The dressings are changed on the fourth or fifth day. The patient may be up in 24 hours and requires only four or five days' hospitalization. The reaction in most instances is slight.

Complications. Infection has not been a complication in any of our 100 operations. When the eye had to be replaced because of dyes fading, muscles becoming loose, or faulty insertion, the tissue from the socket around the implant was found to be lined with a smooth endothelial-like tissue without inflammatory reaction. There has been no postorbital granulation tissue and surprisingly little tissue reaction.

Color changes in the iris are due to body fluids and the dyes themselves. Any

Fig. 11 (Ruedemann). Postoperative patients.

severe reaction to the plastic has not been seen but could occur. Any reaction in the orbital tissue will quiet down. Deep-heat diathermy is contraindicated, for this would change the color of the plastic and the dyes.

Broken wires or muscles pulling loose may be reattached when the eye quiets down. The procedure is difficult, and sodium pentothal or other general anesthesia should be used. Hospitalization is not required. Slight bleeding or discomfort later is usually due to improper covering of the wire ends.

Partial ptosis may result from the eye

being set too deeply or from previous partial ptosis. I measure all globes with Hertel's exophthalmometer, and if beyond 20 mm. I attach the obliques. Discharge is not a complication except with incomplete covering of plates and wire ends.

SUMMARY

Implantation of a plastic eye is time-consuming, painstaking, and difficult. The end results in the appearance of the patient and in his psychologic response justify the effort (fig. 11).

THE EYE EXAMINATION IN THE DIFFERENTIAL DIAGNOSIS OF THE DISORIENTED PATIENT*

BENJAMIN MILDER, CAPT. (MC), A.U.S.

Hines, Illinois

The diagnostic problems offered by the disoriented patient are most frequently encountered in the receiving wards of the larger hospitals. By the expression "disoriented," or "out of contact," we refer to coma, delirium, apathy, or to other psychotic states which render the patient unable to give an adequate history of his condition, or to coöperate voluntarily in the physical examination. The fortunes of war enabled the author to observe some 15 such patients each month in the psychiatric ward of the Veterans' Administration Hospital at Hines, Illinois. Some of these patients were dependent upon the ophthalmologist's findings for a diagnosis; others depended equally on the eye examinations for the elimination of various differential diagnostic possibilities.

Here is a typical sampling of psychotic patients admitted to the psychiatric ward (which composes 20 percent of the beds on the Neuropsychiatric Service).

TABLE 1

ADMISSIONS (NOVEMBER 25, 1944 TO FEBRUARY 25, 1945)

Direct admissions to psychiatric ward	67
Patients, disoriented, directly admitted	40
Percentage, disoriented, directly admitted	60

Many cases of the types listed below were observed on the other divisions of the Neuropsychiatric Service.

In an over-all sampling of admissions to the entire Hospital, it would be found

Published with permission of the Medical Director, Veterans' Administration, who assumed no responsibility for the opinions expressed or conclusions drawn by the author.

that the traumas, brain tumors, and cerebro-vascular accidents are more frequent than is indicated in the foregoing data from the psychiatric ward.^{10, 17, 19}

From these patients, a number have been selected to demonstrate the various disease groupings in which eye findings have been noted. The question of the importance of these findings relative to the

over-all physical picture will be considered.

In an ordinary neuro-ophthalmologic study, the history, visual acuity, visual fields, and ocular-motility studies are largely depended upon for diagnosis. With the noncoöperating patient, we are limited principally to a consideration of the position of the lids, the orientation of the visual axes of the two eyes, gross evidences of trauma, and to the study of the pupils and the fundus oculi. The fundus examination is the *sine qua non* of every neuro-ophthalmologic examination

and must be performed even if it means the utilization of local anesthesia, lid speculum, and fixation forceps.

In each of these cases, an initial tentative impression will be presented, together with the findings on which it was based. Diagnostic studies and historical data will follow, with notation of subsequent revisions of the first impression.

EXOGENOUS TOXINS

ALCOHOL

In order to place the emphasis accurately, it is necessary to begin with the consideration of alcoholic psychoses—one group of mental derangements which presents no pathognomonic eye signs. However, in this institution, these patients form more than one third of all psychotic admissions, and, in the case of accident victims, it is at times necessary to employ our meager eye findings in differentiating between intracranial trauma, traumatic psychosis, and acute alcoholism.

In acute alcoholism, characterized by coma, delirium tremens, or impending delirium tremens, it is common to find dilated pupils, with sluggish reaction to light and limited pupillary excursions. Conjunctival injection, both bulbar and palpebral, is usual. In some patients nystagmus is observed. A very characteristic subjective finding is the presence of visual hallucinations.^{16, 21} Rea³⁰ states that a helpful finding is that of retinal arteriosclerosis, out of proportion to the age of the individual, and he even suggests that one might differentiate the arteriosclerosis of alcoholics from the senile type. One author has observed bitemporal pallor in 20 percent of patients showing alcoholic psychosis.¹⁹

CASE 1. L. J., a white man aged 44 years, was admitted to Hines with complaint of visual hallucinations—moving

circles, polyopia, dogs, and cats. He had been "nervous," with tremors of the extremities, and unable to sleep. He could not remember his actions during the night preceding his hospitalization. He felt that his condition was due to the "flu," but he believed he had been drinking—to help his nervousness—about 1½ pints of whiskey daily.

Physical examination. The patient was somewhat emaciated and had coarse tremors of the extremities and tongue and grossly impaired coordination. There were no other physical findings.

Eye examination. The pupils were moderately dilated, equal, and round, with sluggish reaction to light. Ophthalmoscopic examination showed mild retinal arteriosclerosis, evidenced by increase in the width of the central arterial light streak, and moderate compression of the veins at the arteriovenous crossings. There was no retinopathy. The tentative diagnosis was: Delirium tremens.

At a subsequent interview with the patient it was learned that he had been drinking large amounts of liquor daily for five years. He had had progressively increasing tremors for the past six months, relieved by whiskey. His memory was poor, his intelligence average. He had lost 20 pounds in the past few years. Laboratory reports showed an erythrocyte count of 3,650,000 with hemoglobin of 75 percent.

Final diagnoses were: (1) Psychosis, alcoholic, delirium tremens, recovered. (2) Chronic alcoholism.

DRUG ADDICTION

Morphine and opium addiction are far less common than alcoholism. If the indulgence has been sufficient to effect the victim's cerebration, it is usually possible to note the characteristic miosis.³⁰ There are no other significant ocular findings.

CASE 2. R. A. H., a white man, aged 54 years, was admitted on January 29, 1945. He desired relief from morphine addiction and treatment of precordial pain. The patient stated that he was a heavy drinker, had been suffering from recurrent anginal pain for two years, and had begun to use morphine for relief of the pain.

Results of his physical examination were negative, as were the laboratory findings. The electrocardiogram showed possible old myocardial infarction.

Eye examination. The pupils were 2.0 mm. in diameter, round, and reacted to light. The ophthalmoscopic examination was negative.

The patient had become habituated through the influence of a brother who was a morphine addict, using an average of six quarter-grain doses daily (mild addiction). The patient seemed to have subnormal intelligence, but was well oriented; he was sullen and quietly defensive about attempts to eliminate his addiction. His attitude, at best, was one of passive coöperation. Gradual withdrawal of the drug was effected. The prognosis for continued abstinence was guarded.

Final diagnoses were: (1) Drug addiction, morphine. (2) Psychopathic personality. (3) Coronary arteriosclerosis with myocardial damage.

Comatose or other psychotic states produced by various noxious stimuli (such as barbiturates, carbon monoxide, lead, and arsenic) were not observed during the period covered by this paper. Lead encephalopathy, with epileptiform seizures and papilledema, and barbiturate intoxication, with deep coma and dilated pupils, are encountered occasionally at this institution.^{1, 8, 30}

ENDOGENOUS TOXINS

DIABETIC COMA

One would expect to find a fertile field

for the ophthalmologist in the differential study of diabetic states. The much-described fundus changes^{12, 24} and the frequent hypotony should provide one with an almost certain basis for a tentative diagnosis of diabetic coma. Practically speaking, no such cases were encountered for the reason that the majority of diabetics arrive at Hines with the diagnosis already established.

UREMIC COMA

The same statement does not hold true for uremia. Not infrequently, the ophthalmologist's suspicion of uremic coma, based on the fundus examination, anticipates the results of the emergency blood-chemistry studies.

It is well to remember that there is no single pattern of fundus findings in uremia, for the term refers, not to a disease, but to a state of pathologic physiology (renal insufficiency) seen in the advanced stages of several types of disease. It may result from primary vascular causes, as arteriosclerosis or essential hypertension; or from primary renal pathology, as glomerulonephritis; or the end results of pyelonephritis. Therefore, the retinal changes may be predominantly vasosclerotic, or they may show characteristics of renal retinopathy—cotton-wool exudates, pleomorphic hemorrhages, and, in some cases, a macular star figure. In either event, retinopathy is an almost constant finding. Foster Moore noted its presence in 19 of 20 patients dying of uremia.^{24, 30} Edema may involve the posterior pole of the fundus, or it may be limited to the disc. Preceding a state of uremic coma, the patient may complain of headache, may be delirious, or have convulsive seizures.

CASE 3. J. W., a Negro aged 45 years, was disoriented on admission, showed marked disturbance of equilibrium, and

could not give coherent answers to the questions of the examiner. The patient was somewhat emaciated. He had occasional spasmodic twitching of one extremity and showed a sustained hyperkinesia. His temperature was moderately elevated.

Eye examination. The pupils were equal and round and reacted normally to light and accommodation. Both fundi showed marked arteriospasm, with arteriovenous ratio of 2:4 to 2:5. Sclerotic vessel changes were less pronounced. There were scattered soft cotton-wool exudates and numerous superficial striate hemorrhages. The retina of the right eye showed a 4-disc-diameter area of sharply circumscribed subretinal edema in the superior temporal quadrant. There was no measurable elevation of the discs. Neurologic examination was negative except for generalized cutaneous hypalgesia. Blood pressure was 180/120. Tentative diagnosis was: Toxic delirium of uremia, due to hypertensive renal-vascular disease.

In subsequent consultation with the department of medicine, it was learned that the patient was known to have hypertensive cardiac disease. Laboratory studies revealed an N.P.N. of 200 mg. percent, urea nitrogen of 83.6 mg. percent. Spinal-fluid protein was 90 mg. percent, it being under an initial pressure of 300 mm. of water. Urinalysis showed 2+ albumin, but no casts. At a previous admission, four months earlier, the blood-chemistry findings had been normal; the urine had shown 1+ albumin. Within 48 hours the patient lapsed into coma, from which he did not recover; no significant changes were noted in the retinal picture.

Final diagnoses were: (1) Toxic delirium, due to uremia. (2) Arterial hypertension, systemic. (3) Myocardial insufficiency. (4) Nephritis with nitrogen retention.

The preceding case illustrates one point

in diagnosis which must be considered; namely, the differentiation of toxic delirium associated with hyperpyrexia. In this patient, the characteristic retinal findings, the high blood pressure, and the moderate degree of fever militated against such a diagnosis. However, where the temperature elevation and degree of toxicity are marked (as in typhoid fever, malaria, and pneumonia) the pupils may be dilated, and the ophthalmoscope may reveal retinal hemorrhages.¹² These febrile delirious states are usually diagnosed after the infectious process has been identified.

CEREBRAL VASCULAR DISEASE

CEREBRAL VASCULAR ACCIDENTS

Cerebro-vascular accidents rank high among the causes of disturbances of the psyche, particularly coma. Ordinarily, the ocular examination gives little information regarding the general nature of the vascular accident, whether it be an embolus, thrombosis, or rupture of a cerebral vessel. However, the fundus examination is of some assistance in determining the etiology, especially in hypertension and arteriosclerosis. The pupils and orientation of the eyes are of localizing and, therefore, prognostic value. Anisocoria, with preservation of reaction to light, is common; the dilated pupil is most often ipsilateral to the hemorrhage, and the corneal reflex may be lost on that side. In cases of superficial hemorrhage or involvement of the internal capsule there may be head rotation and conjugate deviation of the eyes, both towards the affected side. Hemorrhage into the pons may induce opposite conjugate deviation, with ipsilateral facial-nerve involvement. In some of the latter lesions, extreme miosis may occur, as a result of irritation of the brain stem.^{18, 20, 24, 27, 32}

In general, the hemorrhages are more likely to induce deep coma and a terminal

picture than are the thromboses. A problem in objective diagnosis—the differentiation of hypertension from brain tumor in the comatose patient who presents papilledema and hemiplegia—will be considered in the discussion of papilledema.

CEREBRAL ARTERIOSCLEROSIS

It is, of course, apparent that the symptom complexes due to arteriosclerosis are innumerable, depending upon the predominant site of involvement. In older patients there are, however, a number of more common characteristic findings. There are tendencies toward impaired motor coordination, amnesia, and defective judgment. Reaction times increase and, in severe cases, the pathologic changes resulting from arteriosclerosis may produce apathy, or coma, quite apart from the vascular accidents which may occur in these patients.²⁴ It is recognized that the presence and degree of retinal arteriosclerosis are not an invariable index of a similar cerebral picture; nevertheless, the correlation is sufficiently high to render the ophthalmoscopic examination of prime importance in the diagnosis of cerebral arteriosclerosis.¹²

The following case history is presented of a man with typical cerebral arteriosclerosis in whom the fundus findings were less pronounced than the cerebral sclerosis. It will be obvious that an initial differentiation between cerebral arteriosclerosis and senile dementia is difficult, but the general picture and fundoscopic examination separate this patient readily from one suffering from uremia, diabetic coma, syphilis, or trauma.¹⁹

CASE 4. J. E. A., a Spanish-American War veteran, aged 73 years, was admitted to Hines on a stretcher. His son, who accompanied him, did not remain for an interview. The patient was completely disoriented: he lay with his eyes closed,

hands folded, in no apparent distress. In reply to most questions, he mumbled: "I am an old man, almost 70!" He spoke of having been dead for two years. His speech was thick, jumbled.

Physical examination. The patient was a huge, obese, entirely uncoöperative old man. Mucous membranes showed dehydration. The blood pressure could not be obtained by auscultation, but was estimated to be 120, systolic, by palpation. Heart sounds were distant. An indistinct mass was palpated in the right lower quadrant.

Eye examination. The pupils and ocular movements were normal. Corneal reflexes were diminished bilaterally, and the left palpebral fissure was slightly wider than the right.

Ophthalmoscopic examination. There was diffuse retinal arteriosclerosis, but the optic discs appeared normal, and there was no retinopathy. The neurologic examination elicited diminished responses to all sensory stimuli. There were no other definite neuropathologic findings.

This patient presented only: (1) mental changes; (2) an abdominal mass; (3) dehydration, and (4) retinal arteriosclerosis. The tentative diagnosis was: (1) Cerebral arteriosclerosis, advanced; and (2) by inference, generalized arteriosclerosis.

Laboratory studies showed a slight albuminuria, negative blood Kahn and Wassermann tests. N.P.N. was 35.0 mg. percent, creatinin 1.4 mg. percent; sugar 121.2 mg. percent, and chlorides 512.0 mg. percent. The leukocyte count was 7,300; erythrocyte count 4,400,000. The spinal fluid was clear, under no increased pressure; the Wassermann reaction was negative, and the gold curve normal (0012221000). The electrocardiogram revealed marked left axis deviation; and the chest X-ray study was not abnormal.

The patient's mental reaction im-

proved somewhat under cautiously administered parenteral fluids. After four days, the son returned and stated that the patient had never been ill until six years ago, when he began to show memory changes, irritability, and loss of appetite. For eight months prior to admission, he had eaten no solid foods and had become progressively less active, remaining in bed for most of the two months preceding hospitalization. The patient remained bedfast, pursuing a gradual downhill course, developed bronchopneumonia, and died on the 23d hospital day.

Final diagnoses were: (1) Psychosis with cerebral arteriosclerosis. (2) Bronchopneumonia, terminal.

Post-mortem examination revealed generalized arteriosclerosis, involving brain, heart, kidneys. There was right hydro-nephrosis and bronchopneumonia.

HYPERTENSIVE ENCEPHALOPATHY

In considering the patient just described, no mention was made of hypertensive encephalopathy as a possible causative factor for the reason that the condition is ruled out, with certainty, by the absence of hypertensive neuroretinopathy. The nerve-head involvement and retinal picture of severe hypertension are invariable accompaniments of the cerebral changes.

The cerebral changes associated with hypertension are characterized by headaches and, in severe cases, convulsions and coma, the manifestations being explained on the basis of anoxia resulting from cerebral edema. Some patients present, on the same basis, a less fulminating picture characterized by loss of orientation, retarded cerebration and other signs of degeneration. There is, in general, a significant correlation between the degree of papilledema, cerebral edema, and the elevation of spinal-fluid pressure.²³ The fulminating encephalopathies are apt to be

characterized by predominance of edematous qualities in the retinopathy, whereas those presenting the picture of mental deterioration will be likely to have a greater sclerotic factor in the fundus picture. The latter group is well illustrated by the following case.

CASE 5. W. F. L., a white man aged 52 years, was admitted to Hines on a complaint of "weakness." He was a small, underweight man, who shuffled about slowly, exhibiting pronounced emotional flattening. He was uncertain whether he had arrived from Chicago or Wisconsin; he believed he was about 40 years of age and had been in the United States since 1926. Identification papers indicated that he had been in the United States Army during World War I. The patient spoke only when questioned and required considerable prodding. He was disoriented for time and place; he showed gross debility of his intellect, and his arithmetic ability was limited to multiplying 2 times 2. There was obvious gross impairment of memory. He was able to care for himself without difficulty.

Neurologic examination. There was muscular wasting with loss of muscle power, but good coördination and no tremors. The cranial nerves were normal, as were the reflexes.

Eye examination. The pupils were 6.0 mm. in diameter and responded to light stimulus with only a limited sluggish contraction. *Ophthalmoscopic examination.* Bilateral papilledema of 2D. was present, with peripapillary retinal edema and numerous hemorrhages and exudates about the discs. In the macula of the right eye were conglomerate small, "hard" exudates, with others scattered throughout the posterior retina. Edema of the macula of the left eye was accompanied by some radially disposed streaks of exudate. The arteries showed marked focal narrow-

ings, with increased central light streak, and the veins showed engorgement and tortuosity. The arterio-venous ratio was 2:4 to 2:5. The tentative diagnoses were: (1) Hypertensive encephalopathy, and (2) alcoholic psychosis, with brain tumor to be excluded.

Further physical examination. A blood pressure of 200/145 was present together with moderate sclerosis of the radial arteries and cardiac enlargement. Results of laboratory studies were: normal cranial X rays; urinalysis and blood Kahn negative; N.P.N. was 35 mg. percent, urea nitrogen 14.9 mg. percent, and blood sugar 112.4 mg. percent. Spinal-fluid manometrics were not done, but the fluid was clear, slightly xanthochromic, with 3 cells per cubic centimeter. Wassermann and gold-curve tests were negative.

Continued observation of the patient discovered no change in signs or symptoms, and the considerations of alcoholism and brain tumor were relegated to the background. The absence of acute cerebral symptoms correlated well with the prominent factor of sclerosis in the patient's neuro-retinopathy.

Final diagnoses were: (1) Psychosis with hypertensive encephalopathy. (2) Hypertension, arterial, with myocardial damage. (3) Arteriosclerosis, generalized, moderate.

SYPHILIS

Acute inflammations (epidemic encephalitis, meningitis, brain abscess) may not properly be considered in this discussion, since they were not encountered on my ward. Of the chronic inflammations, those manifested by a solitary lesion, as for example in tuberculosis, will be considered with neoplasms. Syphilis merits special attention because of characteristic eye findings, and also because of the necessity of recognizing psychotic manifestations of syphilis in accident cases.

The ocular changes of syphilis are too numerous to record in detail here. Patients with meningo-vascular syphilis may show psychic disturbances, depending on the extent of encephalitis, but usually the base of the brain is involved, with ocular-muscle pareses, and unpredictable pupillary abnormalities. More often, in the disoriented patient, the problems of paresis and tabo-paresis must be considered. Here, the Argyll Robertson pupil and ophthalmoscopic findings of primary optic atrophy (both much more common in tabes than in paresis) provide the chief ocular diagnostic support. Paralytic strabismus, usually related to the oculomotor nerve, is uncommon in paresis; such a finding suggests a combination of paresis and tabes dorsalis. The Argyll Robertson pupil occurs in about 50 percent of parietic patients, but other forms of pupillary abnormality are noted; namely, frozen pupils, anisocoria, and dyscoria.^{16, 24, 30}

CASE 6. L. M., a white man aged 50 years, was admitted to Hines for treatment of a fracture of the left humerus and olecranon. The physical examination was negative except for (1) the left arm, and (2) small, irregular pupils. Blood Kahn and Wassermann reactions were negative. Shortly after open reduction of the left elbow was performed, the patient began to show signs of mental deterioration and was transferred to the psychiatric ward for observation.

The patient coöperated well during interview and examination, but showed grossly defective judgment, and his history was later found to be inaccurate. He stated that he had had a diagnosis of syphilis made 10 years ago. The *neurologic examination* was entirely negative except as follows:

Eye examination. The pupils measured 2 mm. in diameter, were irregularly

round, and showed a slight paradoxical dilation to light and reduced constriction in accommodation. The optic discs, retina, corneal reflexes and ocular motility were normal. Despite the negative results of blood tests and physical findings, a tentative diagnosis of paresis was based on the pupillary changes, and the patient's admission of a syphilitic infection.

The Wassermann test, repeated, was again negative, the Kahn was equivocal. Spinal-fluid examination revealed 100 percent positive Wassermann reaction in all dilutions, with a syphilitic colloidal gold curve (0012332100).

Final diagnosis was: (1) Psychosis, with syphilis of the central nervous system, meningo-encephalitic (paresis). (2) Fracture, humerus, left. (3) Fracture, olecranon, left.

One interesting patient presented the problem of differentiation between paresis and posttraumatic psychosis.

CASE 7. R. J. W., a white man aged 54 years, was admitted to Hines for treatment of a fracture of the right leg, both bones, sustained one day earlier.

Physical examination was impossible, on admission, as the patient was agitated, fought with attendants and doctors and refused to permit anyone near him. He was more approachable after 48 hours; he assumed a semistuporous attitude, lying motionless with eyes closed, and responded very sluggishly to commands and questions. He was disoriented, but remembered having been pushed from an "L" platform, as the crowd surged into a waiting train. His memory for subsequent events was poor. His speech was thick and slurred.

The necessity for differentiating between head trauma and posttraumatic psychosis was suggested at first, but the neurologic examination revealed markedly diminished knee-jerk and Achilles

reflex on left, and faulty toe-position sense. (The right lower extremity was in a plaster cast).

Eye examination. The pupils were unequal, that of the right eye measuring 3.0 mm., left 1.5 mm. in diameter. The pupil of the left eye was irregularly round; neither reacted to light, but both reacted to accommodation. The *ophthalmoscopic examination* showed marked yellowish pallor of both optic discs.

A diagnosis of tabo-paresis was now entertained, and was confirmed by the laboratory findings; blood and spinal-fluid Wassermann reaction 100 percent positive; Kahn test, 2+; parietic gold curve (5555432100); negative skull X-ray studies.

Final diagnosis was (1) Psychosis, with syphilis of the central nervous system, meningo-encephalitic (paresis). (2) Fracture, both bones, right leg.

HEAD TRAUMA

The accident victim usually presents no problem with regard to the cause of his disability but, in some cases, gross evidences of trauma and a reliable history are lacking. Approximately 80 percent of patients with head injuries show ocular signs—in most instances, pupillary abnormalities. The pupils are usually small at first, sometimes fixed, as a result of irritation. In shock, they may be dilated, reacting to light. Bilateral, dilated, fixed pupils are considered a grave prognostic sign.¹³ If there is intracranial bleeding or hematoma, one pupil may be dilated, but opinions differ as to whether the dilated pupil is a reliable index for lateralization of the hemorrhage. Dilatation of the pupil resulting from interruption of the afferent pathway may be ruled out by the consensual light reflex.^{20, 33}

Conjugate deviation of cortical origin is usually transient; the direction of the deviation depends on whether the cortex

is irritated (toward) or nonfunctioning (away from).⁷

The fundi may show retinal edema, but papilledema does not ordinarily appear before three to eight days. Peripapillary and diffuse retinal hemorrhages suggest subarachnoid bleeding.^{3, 18} Hemorrhages into the lids and conjunctiva have some diagnostic significance, slow-appearing ecchymosis suggesting anterior cranial-fossa fracture rather than local orbital trauma.³⁴ The following case history illustrates the problems in diagnosis of trauma in the "out-of-contact" patient.

CASE 8. D. M., a white man aged 53 years, was admitted to Hines in a stuporous condition. A taxicab driver had found him lying unconscious in the street, a pool of blood about his head. After some time the patient became sufficiently responsive to recollect that he had set out on a drinking party, but he could recall nothing thereafter.

Physical examination. There was no gross evidence of fractures.

Eye examination. Right eye. The lids were intensely edematous and ecchymotic, with marked proptosis of the eye and orbital contents. The bulbar conjunctiva was ecchymotic and there was massive intraocular hemorrhage.

Left eye. A small subconjunctival hemorrhage was present on the bulbus; the pupil was normal in size and reactions; the fundus showed normal disc and retina with moderate retinal arteriosclerosis. A tentative diagnosis was made: (1) alcoholism, acute (2) hemorrhage, right eye and orbit.

This patient presented the question of differentiating head injury from alcoholic stupor, without the benefit of comparison of the two pupils. The abrupt, massive orbital hemorrhage was not especially indicative of skull fracture, and the fundus of the left eye showed no hemorrhage

nor edema. The patient was observed and showed progressive improvement in his cerebral activity. Skull X-ray pictures showed a probable fracture of the right zygomatic process, but no other evidence of fracture. Spinal-fluid examination was entirely normal.

Final diagnoses were: (1) Psychosis, alcoholic intoxication. (2) Exophthalmos, right, due to orbital hemorrhage. (3) Intraocular hemorrhage, massive, with subconjunctival hemorrhage, right.

BRAIN TUMORS

Any discussion of neuro-ophthalmologic significance will ultimately focus on the consideration of brain tumors, since papilledema may be observed in 80 percent of these patients.¹⁴ Moreover, brain tumor is responsible for about 80 percent of all papilledemas. The expression "brain tumor" is used here to refer to all space-taking, intracranial lesions, benign and malignant, granulomatous or vascular. The signs and symptoms in brain tumor are referable to (1) destruction of brain substance by tumor; (2) pressure on the brain resulting from increased intracranial pressure and cerebral ischemia. Papilledema is a manifestation of the latter mechanism, and is, therefore, of little localizing value. However, because of its frequency, the implications of the finding of papilledema cannot be overemphasized, and it is of paramount importance to be able to differentiate papilledema from optic neuritis, pseudoneuritis optica, and other, similar fundus changes.¹⁴ For the patient's good, a nerve-head swelling must be considered a sign of brain tumor until proved otherwise. Abducens palsy may occur in increased intracranial pressure. Pupillary changes, corneal anesthesia, conjugate ocular deviations, and ophthalmoplegias may assist in the localization of an intracranial mass. Our first consideration, however, is to es-

establish or rule out the existence of a tumor, and although this, as a rule, is a relatively simple matter, pitfalls are many in the disoriented or comatose patient, who usually cannot relate the usual story of headaches, projectile vomiting, convulsive seizures, and progressive mental changes. In some instances, papilledema may be the only objective finding, as is illustrated by the following patient.

CASE 9. F. M., a white man aged 52 years, was admitted because of psychotic episodes, loss of memory, and urinary incontinence. The patient was unable to supply a coherent history. He showed marked emotional swings, and was extremely garrulous. His story centered repeatedly on his past as a baseball player and his inability to remember anything since he became ill. He thought he had been to a place where they had "16 doctors" and where he had had an operation of some sort. He was disoriented for time and place. His conversation was completely incoherent. His response to the question: "Who are you?" was: "Well, let's see, you work for the railroad, I mean the rain—let me see, March, April, May, I can't remember anything since I've been sick." The neurologic examination was negative except for an equivocal left facial weakness and a suggestive Babinski on the left.

Eye examination. The pupil of the right eye was round, 5 mm. in diameter, and reacted to light and accommodation. The left eye was slightly proptosed, and the iris was darker than that of the right. There were no abnormalities of the extraocular muscles. The fundi showed hyperemia of the discs with increased capillary visibility and obliteration of the disc margins. Elevation of each disc was less than one diopter. No hemorrhages nor exudates were found. The remainder of the physical examination was negative.

The tentative diagnosis was: Brain tumor, left frontal.

History from the patient's wife subsequently disclosed that he had had a convulsive seizure 10 weeks prior to this hospitalization. He had been hospitalized elsewhere and studied, with no etiologic findings. After 10 days, the patient began to have memory defects, attacks of amnesia and severe left-sided headaches, and he was again hospitalized. At the second hospitalization, "air X rays" were taken of the brain, and the wife was told that the patient had an inoperable brain tumor, for which the only treatment recommended was a palliative decompression. This treatment was refused, and the patient remained at home until the severity of his headaches made it necessary to hospitalize him at this time. The wife told of a series of attacks of iritis (left eye) during the eight years preceding hospitalization; the last attack, one year ago, was accompanied by secondary glaucoma. Laboratory studies showed slight albuminuria, but no other abnormalities. Skull X-ray films showed only the circular trephine openings of the previous ventriculogram. The chest X-ray study was negative.

The patient was discharged from the Hospital against the advice of the staff and was brought back one month later in terminal condition. He expired within two days. Permission for post-mortem examination was refused.

Final diagnosis was: (1) Psychosis with brain tumor, left fronto-temporal.

The presence of papilledema in cases of brain tumor must be differentiated from papilledema in hypertension (with associated increased intracranial pressure). Erroneous conclusions in this regard may be responsible for serious inconvenience to the patient, as is shown in the following case history.

CASE 10. P. A. J., a white man aged 50 years, was admitted to the Hospital for the treatment of right hemiplegia. On admission the patient was semi comatose, aphasic, and incontinent. His wife stated that he had a "stroke" while working as a brick layer one week earlier. He was unconscious for 24 hours, and had been in a stuporous condition since then. There had been no previous illness, nor mental symptoms, and no direct history of trauma. His physical examination revealed a blood pressure of 180/125, with no cardiac abnormalities.

Neurologic examination. A right facial weakness was established, with severe right hemiplegia and aphasia. Relative hypesthesia was present in the right half of the body.

Eye examination. The pupils and pupillary reactions were normal; the fundi showed bilateral papilledema of 4 to 5 diopters, with hemorrhages confined to the surface of the disc and adjacent retina. The veins were engorged, and the arteries showed moderate generalized attenuation without notable increase in the light streak and with few focal arterial constrictions.

The initial differentiation lay between cerebral hemorrhage, with arterial hypertension, and tumor on the left side of the brain. Spinal puncture was carefully performed. The intrathecal pressure was 400 mm. of water; there were no red cells and no xanthochromia; all other spinal fluid and other laboratory findings were negative. An electrocardiogram was negative.

Influenced by the clear spinal fluid, and by the apparent disproportion between the severe papilledema and paucity of other cardiovascular findings (the blood pressure on some occasions did not exceed 150/95), the neurologists and the writer offered the diagnosis of brain tumor, left fronto-parietal. The ophthal-

mologic consultant in his report recommended further consideration of a vascular etiology, based on the attenuated retinal arteries. Skull X-ray films were normal, except for a slight shift of the pineal to the right. Although conceding that the "onset is rather peculiar for a tumor," the neurosurgical consultant was impressed by the pineal shift, and agreed with the neurologists' diagnosis. An osteoplastic craniotomy was performed. No brain tumor was found, and the dura mater was not under tension. In the motor area, the cerebral cortex was yellowish, softened, and many completely thrombosed small veins were visible; there was evidence of a thrombus in the Sylvian vein.

Final diagnosis was: (1) Cerebral thrombosis, left, with infarction, producing hemiplegia, right. (2) Arterial hypertension, moderate.

Another knotty problem frequently encountered in the psychiatric wards is the ruling out of brain tumor in young adults tentatively labeled as "dementia praecox," "psychopathic personality," or "psychoneurosis, severe." In each instance it is essential to undertake as careful an eye examination as is permitted by the coöperation of the patient.

CASE 11. M. D. D., a white man aged 23 years, was admitted to the Hospital because of amnesia of one week's duration. According to his wife, the patient came home from his job as a bus driver, eight days prior to admission, went to sleep for four hours, and when he awoke he was completely amnesic for his surroundings, family, and his own identity. He went to a movie to "try to remember," but he seemed very apprehensive. His only apparent recollection was that he had a key which he recognized as belonging to his mother's house. He was

hospitalized elsewhere for one week, then transferred to this Hospital.

It was learned that the patient had been going with another woman, had been gambling, and had taken some of the bus company's money to cover his losses. It was felt that the patient's amnesia was on an hysterical basis, as an escape from the consequences of his domestic difficulties. He had previously complained of right temporal headaches.

Physical examination. No abnormality was found except for a fullness (about 5 cm. in diameter) of the skull over the right temple; this prominence was elevated about 1 cm. The *neurologic examination* was also negative.

Eye examination. The pupils were normal, but the eyegrounds showed $1\frac{1}{2}$ D. elevation of the discs with hyperemia and obscuration of the disc margins. There were no hemorrhages nor exudates. The veins were moderately distended, and the arteriovenous ratio was 1:2, but there was no significant venous nicking at the arterio-venous crossings. The fundus picture was interpreted as a probable papilledema, but it was considered "compatible with pseudoneuritis optica." The ophthalmologic consultant made a diagnosis of papilledema, bilateral. Laboratory studies and skull X-ray films were negative.

A tentative diagnosis was made of a space-occupying lesion of the right fronto-temporal region, based on the headaches, amnesia, the bony asymmetry, and the papilledema. The patient's attitude toward his wife and the Hospital was one of hostile suspicion, and he refused further neurologic diagnostic procedures. The final diagnosis was, therefore, not proved but was placed on the record as "brain tumor, probable, right frontal."

Although the patient had adequate basis for a hysterical amnesia (from

which he fully recovered during his hospitalization here), the findings necessitate his classification as a brain-tumor suspect until disproved.

Discussion of the subject of brain tumor would be incomplete without a word concerning the necessity for repeated ocular examinations in disoriented or comatose patients, whether or not they are direct tumor suspects. This is especially true in older persons, to whom the diagnosis "cerebral arteriosclerosis" and "senile dementia" may be too indiscriminately applied.

CASE 12. F. B., a Negro aged 57 years, was admitted for the treatment of psychosis and "stroke." Diagnosis had been made of: (1) Psychosis with cerebral arteriosclerosis; (2) Right hemiplegia, due to left cerebral thrombosis.

Eye examination. The eyegrounds evidenced only moderate retinal arteriosclerosis. The history had indicated some gradual loss of memory and progressive weakness of the right arm and leg. There had been no history of headache prior to admission to the Hospital. The patient had been losing weight for six to eight months.

During the first two months of hospitalization, there was some limited improvement in the hemiplegia, but the patient began to have frontal headaches and lost weight progressively. The weight loss was dismissed as incidental to his chronic illness and bed-ridden state, and analgesics were used for control of the headaches. After two months, he became confused, completely disoriented, and markedly apathetic. Physical examination was repeated, and at this time there were approximately 4 diopters of papilledema bilaterally, with distension and marked tortuosity of the veins. The arteries showed slight attenuation and increase in central light streak. By gross confronta-

tion testing, a right hemianopia was observed. The remaining physical examination showed marked emaciation, blood pressure of 110/72, and liver markedly enlarged to percussion. Neurologic examination confirmed the previous right hemiplegia. At this time, the diagnosis was revised to: (1) Brain tumor, left frontal, probable; "the hemiplegia" was still felt to be on a thrombotic basis.

X-ray films were not helpful. Blood-pressure studies showed no elevation. Blood N.P.N. was 19.2 mg. percent, creatinin 1.9 mg. percent. Léukocyte and erythrocyte counts were normal, as were P.S.P. renal-function test, a G.I. series, and X-ray studies of all bones. On further observation of the fundi, several fresh hemorrhages were discovered. The globulin content of the spinal fluid was increased, but there were no other abnormalities. The neurosurgical consultant concurred in the diagnosis of probable brain tumor, and recommended ventriculography, but suggested that the patient was too ill to warrant the procedure. The patient continued to go downhill rapidly and expired four weeks after the diagnosis of brain tumor was suggested.

Final diagnoses were: (1) Brain tumor, left frontal lobe. (2) Hemiplegia, right.

The pitfalls are many in diagnosis of brain tumor from ocular findings, and each misstep points up the necessity for better and more detailed study on the next patient.

EPILEPSIES

Of the patients admitted to the Hospital for etiologic investigation of epileptic seizures, many were soon recognized as symptomatic of organic brain lesions such as tumor and cicatrices. Of the remainder, the "idiopathic" epilepsies, only a few were observed during seizures.

In these seizures, pupillary changes and abnormalities of the position of the eyes and lids depend on the area of the brain stimulated; thus, the eye findings have a localizing value. In generalized (grand mal) seizures, the eyes may be fixed, staring, or they may rotate upward. In Jacksonian (unilateral attacks), conjugate deviation of the eyes and of the head, to the contralateral side, may be induced; if the facial musculature is involved, an orbicularis spasm may occur.

A simple "adversive" seizure—unconsciousness, with head and eyes turned to one side—suggests contralateral frontal-lobe stimulation. In subcortical (extrapyramidal) attacks, the head is thrown back, and the eyes rolled upward, a position that may be sustained for many minutes. If the diencephalon is involved, the eyes may be wide open and fixed; the pupils dilate during the attack and later contract.²⁹

One mentally deteriorated patient, who was repeatedly observed in grand-mal seizures, illustrates the usual pupillary changes.

CASE 13. C. H., a married white man aged 29 years was admitted to the Hospital because of progressive signs of mental deterioration. One year prior to Hospital admission, the patient had attempted to choke his mother during a quarrel; six months before, he had set upon his grandmother during an argument resulting from his suspicions that his sister was "running around." He had periods of disorientation and poor memory, with occasional delusionary experiences.

The patient's wife, a nurse, stated that he had had epileptiform seizures, at long intervals, for five or six years, and had been under investigation and treatment with dilantin sodium prior to this Hospital admission. There had been several

episodes of head trauma in the patient's lifetime.

His mental examination revealed him to be disoriented, childish in his responses, with loss of memory, and illusionary experiences. Physically, he was tall and slender. He had several healed scalp wounds. Laboratory examinations and spinal-fluid study were without significance. Skull X-ray films showed an old linear fracture line.

During the period of hospitalization, the patient had four epileptic seizures of the grand-mal type. In each instance, there were universal contractions, unconsciousness, and sonorous breathing. The pupils were always dilated during the attack, and on one occasion were noted to be unequal in size. The palpebral fissures were wide; the eyes were not deviated. In the somnolent period following each seizure, the pupils became small again.

The final diagnosis was: (1) Epilepsy, idiopathic (grand mal and petit mal). (2) Psychosis with epileptic deterioration.

THE MAJOR PSYCHOSES

Although the functional psychoses (dementia praecox, paranoia, involutional melancholia) constitute the second most frequent group of admissions to the psychiatric ward, nothing peculiar to these diseases has been observed in the ocular examinations. The examination is important, however, as one of the bases for ruling out organic brain diseases.

Holmes¹⁹ has reported a series of fundoscopic studies in 2,000 consecutive mental patients, in 20 percent of whom he was able to detect eyeground disturbances related to the etiology of the psychoses. Most of these findings occurred

in patients whose psychosis was on the basis of organic cerebral pathologic change—patients of the sort herein previously discussed.

CONCLUSIONS

Since neuro-psychiatric diagnoses are not predicated on eye findings alone, it is not to be considered that this paper subscribes to any such thought. Even for the ophthalmologic consultant, associated physical, neurologic, and laboratory findings must be considered in interpreting eye findings.

Based on examination of disoriented patients at Hines Hospital, the following generalizations may be made:

1. The ocular examination is of greatest significance in the early diagnosis of psychotic and comatose states resulting from: (a) brain tumor; (b) cerebrovascular diseases, especially hypertensive encephalopathy and cerebro-vascular accidents.

2. Of definite value, but less vital than the first group because of the ready availability of pertinent laboratory data, are the eye findings in: (a) uremic coma; (b) syphilis of the central nervous system.

3. In the two largest groups of disoriented patients—(a) acute alcoholism and (b) the major psychoses—the eye findings are of little or no diagnostic value.

4. In (a) diabetic coma and (b) head trauma, the eye findings, while often characteristic, are of little diagnostic significance because pertinent history is usually available.

5. In epileptic seizures, the eye findings may have localizing value in neurologic diagnosis.

OPHTHALMOPEDICS

JOHN J. KOHOUT, D.D.S.

Long Island City, New York

AND ALSTON CALLAHAN, M.D.

Birmingham, Alabama

The frequency of ocular and facial injuries in this war has added new impetus to the art and science of mechanical corrective devices in the field of ophthalmology and plastic surgery. At an Army ophthalmic center* many new ophthalmopedics have been developed.

Each ophthalmopedic is first made up in a combination of paraffin and base-plate wax. The working qualities of this mixture are ideally suited for use in and around the socket.

Depending upon the extent of the injury, undercuts, and compressibility of parts, the procedure in fashioning the wax pattern is by one of three methods: (1) In the direct method, the pattern is made directly on the patient's involved area, such as the socket; (2) in the indirect, the working up of the pattern is based on a plaster or stone model; (3) finally, in the indirect-direct wax-up, the wax pattern is made up on a reproduction of the patient's injury (in plaster or in dental stone), and is then tried and modified to fit correctly in its anatomic position.

After the wax pattern has been invested in a suitable dental flask, it is washed out and the mold is tin foiled. Methyl methacrylate in a heavy, doughy state is packed into the mold and is polymerized for three hours at 100°C. The ophthalmopedic is then polished and available for use.

Irrespective of the method utilized, extreme care must be exercised so that the device is of correct size, shape, and contour. Injury to the skin and mucous membrane is avoided by constructing these de-

vices so that they have no sharp margins or edges, and this is especially true of those which fit inside a socket. At the time of surgery the appliance is sterilized by immersing it in a germicidal solution† for 15 minutes. The entire surface of all appliances enters into contact with the germicide, including the lid-stretcher (fig. 6a). The latter is so constructed as to make its posterior section inseparable from the anterior, when it is in the socket and the lids have been joined by a tarsorrhaphy. Despite the lack of complete disassembly, the openings are made large enough to allow the germicidal solution to come in contact with all surfaces and thus render them sterile. In no case has an infection of the skin or of a mucous membrane followed the use of any of the ophthalmopedics.

With the exception of the conformers and implants required after enucleation, as will be discussed later, each deformity is a distinct problem requiring the construction of a special, individual device. The majority of deformities of the eye and its adnexa do not, however, require such appliances, and it is only at the request of the ophthalmologist that an ophthalmopedic is designed.

1. *Enucleation and Evisceration.* Early in World War II conformers were not universally available. As a result, a few sockets contracted during the interval of time between the enucleation or evisceration at a forward station and the fitting of an artificial eye at an eye center in the continental United States. Later,

* Northington General Hospital.

† Bichloride-of-mercury solution 1:1,000.

when conformers were inserted immediately after removal of the eye, these contractures no longer occurred. Many ophthalmologists use these conformers routinely.

As a standard procedure in 64 enucleations and 8 eviscerations, a conformer,

a perforation through the center for the escape of serum (fig. 1). We have seen no localized reaction from the use of socket conformers; on the other hand, they served to shorten postoperative recovery.

After enucleations, the implant used has been an acrylic sphere with serrations

Fig. 1 (Kohout and Calahan). Conformers for the conjunctival cul-de-sac after enucleation.

Fig. 2 (Kohout and Calahan). Implant spheres made of methyl methacrylate.

thinly coated with 5-percent sulfathiazol ointment, was inserted into the conjunctival cul-de-sac immediately upon the completion of the operation. The conformer assists the external elastic bandage to maintain the pressure on orbital tissues and prevent hemorrhage, makes impossible the prolapse of conjunctiva through the palpebral fissure, and maintains the surface area of the conjunctiva. Our conformers vary in size from 25 mm. by 20 mm. to 35 mm. by 25 mm. and have

(fig. 2), and we have observed only one extrusion.

2. *Contracted sockets.* Phimotic sockets due to the detachment of a canthal ligament, especially if no conformer has been inserted, present a difficult problem. This is overcome by using successively larger conformers (fig. 3a) which gradually increase the size of the socket. Progress was more rapid when a small mediolateral expanding device was in-

Fig. 3a (Kohout and Callahan). Successively larger conformers which gradually increase size of sockets. After the expanding device had been opened as fully as possible, it was closed, the caps were applied, and expansion continued. The entire procedure from the smallest to the largest size required five months.

sented. This was gradually opened, and later caps were added to produce further enlargement. Five months were required to expand the smallest socket to one amply accommodating a plastic eye (fig. 3b).

When a socket is reconstructed with skin, the exfoliation, discharge, serum,

and the like often interfere with good results. To maintain an ample fundus and to keep it cleansed, a special conformer with an irrigating system was devised (fig. 4). It may be placed in the socket

Fig. 3b (Kohout and Callahan). Mediolateral socket expander in place.

Fig. 4 (Kohout and Callahan). The flat base maintains the socket, is kept in place by subtotal tarsorrhaphy. The protruding barrel is placed at the inner canthus, and a standard syringe fits into it for irrigation with antibacterial solution.

at the conclusion of surgery and maintained *in situ* by a subtotal tarsorrhaphy until all contraction of the graft has ceased. Several times daily, the conformer may be flushed with cleansing solutions, or such antibacterial solutions as penicillin, the fluid being directed into the system by a syringe.

Occasionally entropion of the lower lid or a very shallow inferior fornix will develop as the socket contracts. If pressure is applied to the lid from the orbit by means of an apparatus which expands in its lower portion only, the entropion, in some cases, may be corrected without surgery (figs. 5a, b, c).

3. *Wrinkling of the skin in lid reconstruction.* In anophthalmic cases, after reconstruction of the upper or lower eyelid, or both, marked wrinkling of the graft has sometimes occurred despite a tarsorrhaphy. An instrument to correct this complication was suggested by Capt. Jerome H. Cohen (MC) and Capt. Seth Barron (MC). It consists of a posterior segment which rests against the orbital

tissues and an expandible anterior portion. In the first model, expansion was accomplished by a mineral-oil "pressure chamber," but this system had the disadvantage of requiring a cut-off valve, and the obvious defect of being subject to leakage. It was, therefore, discarded.

A lid stretcher, based on a mechanical-screw principle (fig. 6a), was evolved by the same investigators. It is placed in the socket, and after the adhesions of the

Fig. 5a (Kohout and Callahan). Force is applied to the inside of the lower lid, helping to lessen and sometimes even to correct entropion.

Fig. 5b (Kohout and Callahan). Cicatricial entropion, right lower lid. (Surgery by Lt. Col. John Pick.) Fig. 5c, Correction of entropion by device shown in figure 5a.

tarsorrhaphy have firmly united, the screw is turned, causing stretching—and therefore smoothing—of the skin (figs. 6b and c).

Fig. 6a (Kohout and Callahan). Turning of the screw causes separation of the anterior from the posterior segment. The two small guides prevent rotation of either section. There are small flanges at the end which prevent the separation of the segments.

4. *Edema of the lids.* In many cases of traumatic anophthalmos there is no support for the upper lid; and frequently, after dislocation of a lower lid, it hangs without support. Edema occurs because venous and lymph return is very poor.

Because of this and the additional factor of gravity, a cycle of reciprocal pathologic changes develop. As the edema increases, the lower lid acts as a valve closed upon itself. This defective metabolism lowers the vitality of the lid and increases the difficulty of reparative surgery.

The usual compression bandage rarely exerts the exact pressure required, and must be changed very frequently because of discharge around an abnormal socket. Lack of exposure to light and air often depresses the vitality of the tissues.

To overcome these disadvantages, external supports were developed for such lids, consisting of acrylic prostheses which use the most convenient bony support—the nasal, zygomatic, maxillary, and temporal bones (figs. 7a, b, c, d). In certain cases where external pressure alone was insufficient to give proper support, these devices were modified so that a portion extended inside the lid, and the latter was thus supported both from the anterior and inferior aspects (figs. 8a, b). A combined device to aid in rebuilding the socket with a ledge for the support of the upper lid is one of the many modifications possible (fig. 9).

Fig. 6b (Kohout and Callahan). After reconstruction of upper and lower lids, the graft shows considerable wrinkling. Fig. 6c, A subtotal tarsorrhaphy holds the lid stretcher in place. In three months, there has been considerable smoothing of the graft. (Surgery by Major Clement C. Clarke.)

Fig. 7a (Kohout and Callahan). Edema of lower lid which has assumed almost tumorlike proportions. The white discharge seen on the lower lid is pyocyanic discharge. Fig. 7b, Lateral view.

Fig. 7c (Kohout and Callahan). Acrylic pressure conformer in place. Fig. 7d, Appearance after two months just prior to surgery.

Fig. 8a (Kohout and Callahan). A shell fragment has caused loss of right eye, floor and medial wall of orbit, lateral wall of right nasal cavity, part of septum, and left lower lid. Upper lid, unsupported, is edematous. (Surgery in this case performed by Major Arthur J. Barsky.)

5. *Ptosis of the upper lid.* After an injury which has resulted in ptosis of the upper lid, four to eight months are usually allowed to elapse before reparative

surgery is undertaken, since partial and occasionally almost complete restoration of function may occur. Although the eye may possess normal vision, it will be

Fig. 8b (Kohout and Callahan). The support given the lid reduces the edema rapidly.

Fig. 10 (Kohout and Callahan). Ptosis of the lid from trauma. The upper lid is supported by this device during the period of possible recovery, giving binocular vision.

Fig. 9 (Kohout and Callahan). This device is inserted in the socket, and pressure is exerted by adhesive tape attached to the forehead and cheek over the bar.

Fig. 11a (Kohout and Callahan). Plastic artificial eye with prominent superior ridge.

valueless during this time because of the ptosed lid. A device has been originated which permits binocular vision by elevating the lids during this period of observation (fig. 10). Even in cases wherein no restoration of function of the levator occurred, the local muscle tone may have improved.

6. *Ptosis of the upper lid with anophthalmos.* When there is no action of the levator palpebrae and the eyeball has been lost, it is often unnecessary to emplace a fascial sling or perform other types of repair for blepharoptosis. In our series, 12 of 16 cases have been satisfactorily corrected by the insertion of a plastic artificial eye made with a prominence on the upper border as shown (figs. 11a, b, c).

7. *Rapid settling of the socket.* In the process of making a plastic eye, one of the last steps in the procedure is the removal of the anterior "stem" from the center of the cornea. To hasten the seating of the artificial eye in certain sockets where it assumes an "exophthalmic position" a T-shaped pressure device has been made which may be slipped upon the stem. By using a strip of adhesive tape as a brace, this device shortens the time otherwise required for the final positioning of the eye (figs. 12a, b, c).

Fig. 12a (Kohout and Callahan). The T-shaped pressure device which may be slipped upon the "stem" of an artificial eye.

8. *Complete loss of eye, lids, and orbit.* Major surgery of the orbit and lids is required for the correction of this condition. Proper caution must be employed because of the proximity to meningeal and cerebral tissue. Even at best, a long period of hospitalization is required. Certain selected cases can be handled preferably by the use of an external prosthetic device combined with the usual spectacle frame (figs. 13a, b, c, d).

THE THERAPEUTIC TREATMENT OF UVEITIS ASSOCIATED WITH TOXOPLASMOSIS*

ARLINGTON C. KRAUSE, M.D., AND LAWRENCE F. SMITH, M.D.

Chicago

The method of treating ocular disease associated with an apparent active infection of toxoplasmosis may be based primarily on the suppression or the elimination of toxoplasma in the body and secondarily upon the local manifestations of the disease. This paper is concerned with the general therapy of ocular toxoplasmosis.

A very few reports mentioning the use of drugs in cases of toxoplasmosis have been published. Sabin and Warren¹ have tested a series of drugs by experimental methods. Atabrine, trypaflavin, potassium antimonytartrate, rivanol lactate, optochin, mapharsen, neosalvarsan, tryparamide, and quinine hydrochloride killed toxoplasmas but had no therapeutic effect when used on infected animals. Fouadin, stibosan, silver salvarsan, bismuth subsalicylate, sodium aurothiomalate, sodium iodide, methylene blue, and Bayer 205 had no influence on the infection. Only the sulfa drugs had curative properties although they were harmless *in vitro*.² Sulfanilamide was only slightly beneficial. Sulfapyridine and sulfathiazole cured infected mice only when a high blood level of the drug was maintained. They arrested a severe infection in mice, but the immunity was not increased. In rabbits, the immunity was developed during the drug therapy, and the animals remained cured. Biocca and Pasquali³ confirmed the experience of Sabin with the therapy of the sulfa drugs on mice.

The action of sulfa drugs on patients has not yet been evaluated. Pinkerton and Henderson⁴ found that sulfanilamide

was ineffective in a fatal case of toxoplasmic encephalitis. Sabin⁵ tried the same drug on a child. Zuelzer⁶ used sulfadiazine and sulfamerazine in three cases. One child survived. The dosage was not reported. Cowen *et al.*⁷ gave sulfathiazole to one patient. In all of these cases the effect of sulfa drugs was unknown or not demonstrable. Vail *et al.*⁸ treated one patient twice with typhoid vaccine and with 15 grains of sulfathiazole every four hours for 37 doses. The uveitis became inactive. Later the uveitis reappeared, and the sulfathiazole therapy was repeated. When the ocular disease became worse, sodium iodide was given and the condition improved. A second patient was given typhoid vaccine and later tuberculin injections, without effect.

About 70 cases which have given positive intradermal protective tests for toxoplasmosis have been seen up to January 1, 1945, in the section of ophthalmology of the University of Chicago Clinics. Fifty of these cases have been studied with the purpose of evaluating the effects of various treatments. The results of the study are recorded in this paper. The clinical progress of each case was outlined to bring out any relationships which might exist between treatment and changes in the patient's condition. The evaluation of the results of the treatment were based on: (1) subjective impressions of the patient; (2) changes of vision; (3) state of activity of the disease as indicated by the amount of hemorrhage, exudate, and scarring; (4) change of the visual field. It was customary to give several patients a combination of medicines rather than one alone. In such cases, the results have been attributed

* From the Section of Ophthalmology, Department of Surgery, University of Chicago.

equally to the members of the combination unless there was more favorable evidence for one drug in certain cases than in the other cases. Although some therapeutic measures were initiated at a time when the disease was regressing or quiescent, the results are not without significance since this disease appears to be one of constantly fluctuating activity. A drug would be of importance if it could prevent recurrence as well as halt progress.

Eighteen of these 50 cases received no treatment. Twelve of these 18 were inactive when first seen and remained so while followed. However, most of these cases were seen only once or twice over a one- or two-month period. Three of the 12 cases were seen over longer periods (6, 10, and 24 months). Five of these 18 cases showed some activity but received no general treatment. These five were seen over periods of two to seven months and only one of them showed any change in degree of activity.

Fourteen patients received typhoid-vaccine injections as fever therapy; eight received sulfonamides (that is, sulfanilamide, sulfadiazine, sulfapyridine, or sulfathiazole) at the same time, and one, para-amino-benzoic acid. In 8 of the 14, improvement was noted, either temporary or permanent, within four days to three weeks after treatment. Seven of these eight were patients who received sulfonamides (or para-amino-benzoic acid in one case) at the same time. The patient who was treated with sulfanilamide became worse. Of the five patients who received triple-typhoid-vaccine injections alone, four were apparently unaffected by treatment, one possibly was improved. In one case the eyes had grown worse three weeks following treatment, but since this change occurred such a long time later there would be little justification in attributing it to the treatment.

In the eight cases which improved fol-

lowing triple-typhoid-vaccine injections and (except in one case) administration of sulfonamides or para-amino-benzoic acid, the treatment appeared to be helpful. Furthermore, the combination of triple-typhoid vaccine and sulfonamide drugs appears to have been more beneficial than triple typhoid alone. The courses of typhoid-vaccine-fever therapy consisted of three to five injections, varying from 15 to 130 million units and given over a period of 7 to 14 days. The fever ranged from 102° to 104°F. by mouth. Those patients who received sulfonamides were given 4 to 7 gm. per day during the fever therapy. The para-amino-benzoic acid was given in 4- to 7-gm. doses on two days.

Two cases were treated with sulfathiazole and sulfamerazine. One case was in a state of regression, and the course remained unaltered with sulfamerazine. The other case was not benefited by sulfathiazole alone. About two months later the same patient received injections of triple-typhoid-vaccine shots and sulfadiazine, and his condition underwent a subsequent regression of activity. These data suggest that the combination of triple-typhoid vaccine and sulfonamide was more effective than sulfonamides alone. The sulfonamides were given in doses of around 3 gm. per day for two to three weeks.

In 5 of the 11 cases treated with atabrine and plasmochin there was inactivity, regressing activity, or little activity when treatment was started; in regard to these, it may be stated that there were no exacerbations during medication and that the drugs did no harm. Of the remaining six cases, five showed improvement from the drug. One outstanding feature of the last four of these cases was the marked subjective improvement following administration of the drug. There were also some objective signs of improvement.

Little may be said by way of comparison of the atabrine-plus-plasmochin combination and atabrine alone, for the former was used mainly in the treatment of inactive cases. Atabrine was administered as atabrine hydrochloride, 50 to 200 mg. per day for periods of 2 to 14 weeks; these periods were interspersed with periods of alternating therapy with plasmochin plasmoate, 20 mg. per day, by the week.

Ten cases were treated with potassium iodide. In one of these, there was evidence of improvement during the five weeks following treatment. However, the patient was receiving trythrityl tetranitrate at the same time. In another, the lesion showed progression three weeks after treatment was started. The question then arose whether or not the drug did any harm. However, since the drug had an indifferent effect in eight other cases, in six of which there were active lesions when medication was started, this seemed unlikely. Potassium iodide appeared to be ineffective.

Three cases treated with proteolac showed no effect from treatment, and three possibly benefited. However, the response of the last three was slow or minimal. This treatment may be said to have slight therapeutic possibilities. The proteolac was administered intramuscularly in doses of $1\frac{1}{2}$ to 2 c.c. every day or on alternate days for periods of 20 to 30 days.

Five cases, four of them active, were treated with quinine. No changes were noted following treatment. Quinine appears to be ineffective. The patients were given 5 to 20 gr. per day for two weeks to four months.

Erythrityl tetranitrate had no appar-

ent effect in three cases while three other cases showed questionable benefit. This drug appeared to be of little value in this treatment. It was given in 30- to 90-mg. doses per day for periods of five weeks to three years.

Old tuberculin was used in two cases of chronic choroiditis and one of chronic iridocyclitis without any good evidence of improvement. The treatment was given over a period of about six months and comprised around 25 injections of increasing strength from 0.05 c.c. of 1:10,000 to 1.8 c.c. of 1:1,000 dilution.

Various other therapeutic treatments were tried. Brewer's yeast appeared to have been of questionable benefit in a case showing a fairly typical picture of the disease. In one case X-ray treatment seemed to stop recurrent bleeding into the vitreous humor. Calcium lactate, Fowler's solution, citrus-fruit juices, nicotinamide, nicotinic acid, thionine chloride, vitamin-B complex, papaverine hydrochloride, and sodium nitrite induced no improvement. One million units of penicillin given in doses of 100,000 units every three hours for two days proved valueless.

CONCLUSIONS

At the present time the presumptive evidence is that the sulfonamides—sulfadiazine, sulfapyridine and sulfathiazole—with typhoid-fever therapy may have value in the treatment of uveitis associated with toxoplasmosis. Sulfonamides alone seem to have little or no effect on the disease. Atabrine apparently gives some subjective and objective improvement. Penicillin, vitamins, potassium iodide, and vasodilators produced no demonstrable change in the course of the disease.

EXOPHTHALMOS CAUSED BY EOSINOPHILIC GRANULOMA OF BONE*

MAYNARD WHEELER, M.D.

New York

Eosinophilic granuloma of bone is a relatively new disease entity. A few isolated reports of cases showing similar pathologic change appeared in the literature between 1929 and 1938 (Frinzi, Mignon, Fraser, Schairer) but it was not until 1940 that articles were published which recognized the clinical and histologic picture as a distinct entity. In that year Otani and Ehrlich gave it the name of "solitary granuloma of bone," while at the same time, and independently, Jaffe and Lichtenstein used the name "eosinophilic granuloma of bone" which they considered more descriptive. This latter name has been quite generally accepted by subsequent writers. At least 37 cases have now been reported.

The clinical features of eosinophilic granuloma are a rapidly developing painful swelling over the skull, a rib, or a long

bone, in a child or young adult. In many cases multiple lesions have been found by the X-ray, but in practically every instance there was only one that gave symptoms. Lesions have been found in the frontal bone in at least seven instances but in only one case, a girl of four years (Gross and Jacox), has exophthalmos been reported. The diagnosis is made by histologic examination, for there is nothing distinctive about the X-ray findings. The pathologic picture is unmistakable and will be described in the following case report.

REPORT OF CASE

A young man, aged 34 years, was seen for the first time on August 23, 1944. His right upper lid had begun to swell five weeks previously. He then developed pain behind the eye. The swelling varied; the vision was blurred when the swelling was marked.

Examination. Vision was 20/15 in each eye. The muscle balance was normal. There was an exophthalmos of the right

*From the Institute of Ophthalmology of the Presbyterian Hospital. Presented at the 81st annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, November, 1945.

eye of 2 mm., the globe being displaced downward about 4 mm., but without limitation of motility. No mass was palpated. The fundi were normal. No enlarged lymph nodes were found.

X-ray report. Dr. Pfeiffer reported the orbital X-ray studies (fig. 1) as follows: "The right orbit shows a fairly circular defect through the roof, measuring approximately 2.5 cm. posterior to the outer half of the upper margin. The margins of this defect are slightly irregular and show no tendency to increased density of the bone. The defect extends upward perhaps a centimeter and appears to be covered throughout by the inner table, although this cannot be stated with certainty. The defect is cystic in appearance and does not communicate with any of the paranasal sinuses; it is more suggestive of an epidermoid than of anything else, although the margins of the defect are not sharp and do not show increase in bone density."

Operation. On the following day, the right orbit was entered through a lateral canthotomy. In retrospect, it is realized that it would have been better to approach the tumor through an incision below the lateral third of the brow. The tumor was located, after considerable difficulty, in the region of the lacrimal gland. It was a flattened, firm swelling lying above the lacrimal gland and extending back about 3 cm. into the orbit, along its superolateral wall. No definite capsule was encountered, but when the mass was opened a soft, pinkish-cream-colored material presented. At first this looked like the sebaceous material found in a dermoid cyst; further exploration, however, showed that it was not cheesy but rather very soft, partly necrotic,

granulation tissue. It was too soft to remove with any instrument other than a large curette used as a spoon. Throughout the mass were many small spicules of bone, and the bony wall was extremely irregular. Because of the poor exposure afforded by the small incision, the exact size of the mass could not be determined,

Fig. 1 (Wheeler). X ray of the orbits, before operation, showing the large defect in the roof of the right orbit.

but the cavity was thoroughly curetted. The incision was closed tightly, an intermarginal suture placed, and a firm pressure-dressing applied.

Postoperative course. The patient's recovery was uneventful until the preauricular lymph node became enlarged, about 10 days after the operation. This caused some uneasiness on the part of both the patient and the doctor, but it gradually subsided and now, nine months after the operation, there is no evidence of recurrence, although there is still about 1 mm. of exophthalmos. X-ray studies at this time show: "the inferior portion of the lesion of the roof of the orbit to be healed with the defect largely filled in." X-ray films of the skeleton failed to show any other lesions.

Pathologic examination. The specimens were composed largely of necrotic granulation tissue (fig. 2) containing large numbers of histiocytes, many of which showed evidence of phagocytic activity and occasional large multinuclear giant

The youngest was 2 years old. Thus it is a disease of children and young adults.

Diagnosis. Because of the tumor's rapid growth and the X-ray picture of a localized lesion starting in the medullary cavity and tending to erode, expand, and perforate, a malignancy is frequently suspected. The X-ray appearance must be differentiated from primary carcinoma, bone cyst or osteomyelitis, multiple myeloma, Ewing's tumor or a metastatic tumor, and now, for the first time, from an epidermoid. The final diagnosis must be made by histologic study, and in this case probably an aspiration biopsy would have sufficed. The characteristics have been described and are quite distinctive.

Etiology. Attention should be called to the theory of Farber that eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe's disease represent different stages in the same basic disease process. This has been ably set forth by Mallory. Letterer-Siwe's disease (aleukemic reticulosis or nonlipoid histiocytosis) always occurs under two years of age and is rapidly fatal. It is char-

acterized by marked proliferation of the reticulo-endothelial cells, particularly in the skin, lymph nodes, and spleen. Hand-Schüller-Christian disease, characterized by multiple defects in the cranial bones, exophthalmos, and diabetes insipidus, occurs a little later in life and is less malignant in its course. The pathologic picture is that of a granulomatous process accompanied by significant grades of inflammatory reaction, both leucocytic and fibrotic. Eosinophilic granuloma of bone

Fig. 2 (Wheeler). High-power photomicrograph, showing large multinuclear giant-cell and numerous histiocytes, some in various stages of necrosis.

cells. There were also numerous eosinophilic and neutrophilic leucocytes and many clumps of mononuclear cells taking an eosinophilic stain. Occasional bits of bone were found.

DISCUSSION

Age. Only two cases have been reported in which the patients were older than the man described here (Otani and Ehrlich, 35; Versiani and Figueiro, 50).

appears at a still later age and is much milder in its manifestations. Farber found every grade of transition from the typical Hand-Schüller-Christian disease to eosinophilic granuloma. Otani and Ehrlich tried to establish the relation between eosinophilic granuloma and trauma. Jaffe and Lichtenstein, who are in accord with Farber and Mallory, believe that the basic anatomic disorder in these three conditions is a peculiar inflammatory histiocytosis, possibly caused by a filterable virus.

Treatment. Because of the uncertainty as to the etiology of these lesions and the strong clinical suggestion of malignancy, they have been treated in various ways: by wide excision or by curettage, both

with and without X-ray therapy; and by the X ray alone. Apparently all the patients have recovered.

CONCLUSION

A case of eosinophilic granuloma of bone, in which unilateral exophthalmos was the presenting symptom, is described, with a brief discussion of the salient features of this relatively new entity.

The author wishes to express his gratitude to Dr. William L. Gills for kindly permitting him to present this case, to Dr. Raymond L. Pfeiffer for his interpretation of the X-ray studies, and to Dr. Algernon B. Reese for his aid in the pathologic study.

PLASTIC-ARTIFICIAL-EYE PROGRAM, U. S. ARMY

STANLEY F. ERPF,* MILTON S. WIRTZ,[†] AND VICTOR H. DIETZ[‡]

There is little doubt but that creative thought arising from military exigency has made important contributions to the progress of medical sciences in the recent conflict. The many accomplishments of all branches of the Medical Department of World War II speak for themselves. The ingenuity and diligence of both military and civilian personnel in wartime service in the face of tremendous odds merit commendation.

The task of rehabilitating our fighting men to more peaceful pursuits is beginning to draw to an end. With the proof of many hypotheses before us, it is now possible to assume a more objective viewpoint of what actually has been accomplished during the past few years.

In this connection, it is interesting to observe how one problem, the supply of artificial eyes to military patients, was

faced by the U. S. Army Medical Department.

HISTORICAL BACKGROUND AND PROBLEM

The world's supply of glass artificial eyes, particularly the iridial portions thereof, was, and still is, controlled for the most part by the members of one German cartel. Formulas for the special type of glass required, and details of the technique employed in the manufacture of the iris component are not generally known, although at least one American glass manufacturer has been at work for some time on the problem of developing an adequate substitute.

With the advent of World War II, German exports to the United States and allied countries were brought to a sudden halt. True, a few stock glass eyes and irides found their way into this country, but the supply was far from adequate in meeting even civilian demands, let alone those of the military. The critical nature of this emergency was further aggravated by three factors: First, glass eyes require frequent replacement because of break-

* Major (DC), A.U.S., Dibble General Hospital, Assistant Professor, University of California (on wartime leave).

[†] Major (DC), A.U.S., Fitzsimons General Hospital.

[‡] Major (DC), A.U.S., Halloran General Hospital, Instructor, Washington University (on wartime leave).

age, surface etching, and discoloration. Second, the anophthalmic socket and adjacent structures will not wait long for reception of prosthesis without changing size, shape, and tonicity. Unless a suitable restoration is placed within a reasonable length of time, the percentage of cosmetically acceptable prostheses is considerably reduced. Third, the average stock glass eye is not adequate for use in cases of military nature where lacerated, lost, or crushed tissues have required extensive surgical repair.

For these reasons, the few glass-eye makers in America capable of making custom-built prostheses were faced with the impossible situation of supplying the demands of the military as well as caring for the needs of their civilian clientele. Likewise, stocks of glass artificial eyes rapidly dwindled to the point where only a few utilizable prostheses remained.

It was not long before patients in military hospitals in the United States and overseas were constituting a considerable backlog because of the unavailability of a satisfactory supply of artificial eyes. In desperation, odd sizes, shapes, and colors of stock eyes were inserted in patients for whom custom-made prostheses were obviously indicated. Embarrassment and deterioration of patient morale resulted. Much dissatisfaction was registered.

As has been mentioned, similar situations existed in allied countries. Shortly after the onset of the war, when it was apparent that supply would not meet demand, the British established a school for women in this field. In spite of the excellent job done under the existing conditions, lack of special glass and technical "know how" left something to be desired. The Russians, too, were having their difficulties and were reputed to have resorted to the use of eye patches with the intention of placing restorations at

such time as an adequate supply of artificial eyes might be forthcoming.

It is obvious, then, that a large number of restorations was urgently required by the Medical Services of all allied countries. This was imperative not only for the reason of preventing total depletion of the civilian supply but also to fit patients who were already hospitalized. Still more important, it was necessary to prepare for demands of the days yet to come.

A number of requirements had to be satisfied in this connection. Restorations of a more durable substance than glass were desirable. The prostheses would have to be as natural or more natural in appearance than those of glass. A material had to be used which could be produced easily and which would lend itself readily enough to routine technical procedures, necessitating only a minimum of technical skill and laboratory equipment. A rapid teachable method had to be devised which could be standardized to the point where component parts of the prosthesis might be prefabricated, then assembled, modified, and adjusted to meet the patient's individual requirements. These requisites were of paramount importance in the military service during the recent emergency.

TRAINING OF ARMY PERSONNEL

In answer to the challenge existing in the European Theater of Operations in the early days of the war, one of us (S. F. E.) began to adapt dental materials and technique to satisfy the requirements mentioned. Although this initially designed plastic eye, with its hand-cut iris recess and scribed and painted veins, was somewhat crude, judged by present Army standards, the results were satisfactory considering the necessarily improvised equipment used at that time.

On the basis of this early work, and through the foresight of Maj. Gen. P. R. Hawley, then Chief Surgeon, E.T.O., Dr. Derrick T. Vail, then Colonel (MC), Senior Consultant in Ophthalmology for the European Theater of Operations, Col. William D. White, then Chief Dental Surgeon, European Theater of Operations, and Col. D. H. M. Stanley (MC), then Commanding Officer of the 30th General Hospital, a training center for ophthalmoprosthetists was organized in England, in December, 1943. A technical manual¹ for student use was written at that time, and 40 dental officers from U.S. Army General Hospitals were selected for training. The British War Department also assigned 10 dental officers of the British Army, Royal Navy, and Royal Air Force for training in the technique.

In the meantime, the situation with regard to the supply of artificial eyes to Army personnel still persisted in the United States, although mitigated to a considerable extent by the efforts of two of us (V. H. D. and M. S. W.). At Thomas M. England General Hospital in Atlantic City, New Jersey, and Camp Crowder, Missouri, respectively, these men were also at work on the problem of developing an adequate substitute for glass artificial eyes.

Realizing that the combined efforts of the authors would expedite the development of a standardized Army technique, Major General Norman T. Kirk, the Surgeon General, placed the overseas school in charge of Colonel Lynn C. Dirksen, Dental Corps, and brought the authors together under the administration of Mr. Stanley W. Rybak, Supply Division of The Surgeon General's Office. It was felt at this time that the program would function more advantageously if placed in closer liaison with the Medical Department activity which it was to serve. For this reason, executive policies

were established by such men as Lt. Col. M. E. Randolph, Col. Derrick T. Vail, and Major Trygve Gundersen, all of the Office of Ophthalmology, Surgeon General's Office, U. S. Army. Research by the authors was intensified under this organization. The desirable features of three respective techniques were combined and improved features added.

In September, 1944, a second technical manual² for student use was written, and a 30-day course of training conducted for 12 dental officers. Upon termination of the training period, these men and their instructors were assigned to various general hospitals throughout the country and overseas. They, in turn, trained other officers and technicians. Supervision of these installations and conferences concerning policies were regularly conducted. One year later, in October, 1945, 30 installations had inserted over 7,500 all-plastic artificial prostheses for patients, many of whom would otherwise have been forced to accept inadequate glass eyes. This figure is in addition to those restorations made by the initial trainees still operating in the European Theater of Operations.

The various installations are now in the process of being demobilized, as military demand for artificial eyes decreases. Attention is at present being directed toward the organization of a program and training of personnel for the Veterans Administration.

Due credit must be given the excellent work of the Navy in development of acrylic eye prostheses for their branch of the service.^{3, 4, 5}

JUSTIFICATION FOR SELECTION OF DENTAL PERSONNEL

In any military emergency, speed is an important factor in returning hospitalized men to duty. Since the particular technique employed in fabricating eyes

was one which could be rapidly mastered by individuals familiar with dental procedures, dental officers and technicians were selected. In actuality, little more instruction was required beyond the giving of a few measurements and technical shortcuts. With the streamlined teaching method employed, the trainee was familiarized in short order with the oil painting, impression taking, mold construction, compounding and processing of plastics, and fitting as applied to plastic-artificial-eye construction. After two weeks of instruction, the average dental officer with previous specialized experi-

to compensate for socket irregularity so frequently observed in cases of military nature.

3. Adaptability of various other features, such as the corneoscleral junction, depth of anterior chamber, diameter of iris, pupillary aperture, vascularity, and sclera color, to meet individual esthetic requirements. This is possible only because of the strictly anatomic assembly of parts throughout.

4. An actual three-dimensional effect in iris construction due to suspension in clear resin of a perforated transparent disc which has been painted on both sides.

Fig. 1 (Erpf, Wirtz, and Dietz). The iris disc.

ence in dental prosthesis, was capable of fabricating acceptable eye prostheses. It may be mentioned that some ophthalmologists showing interest in this field have demonstrated their ability to perform the various technical procedures involved.

THE TECHNIQUE

The technique produces plastic artificial eyes^{6, 7, 8} incorporating the following advantages:

1. Freedom from fragility and surface etching occurring as a result of dissolution by socket secretions.

2. Adjustability of size and form during and following fabrication in order

The three-dimensional effect mentioned is further enhanced by placement of a jet-black pupil disc at some distance posterior to the iris disc.

5. Opportunity to stock prefabricated iris buttons, enabling the operator to know at the outset the exact color of the iris in the completed prosthesis.

6. Elimination of such time-consuming steps as multiple-mold construction, precision grinding of the iris recess, and engraving for simulation of veins as required in plastic prostheses of the conventional type.

7. Teachability of method in so far as dental personnel may be trained to under-

take all phases of fabrication after a relatively short period of instruction.

The technique of fabrication is divided into eight steps. Briefly described, they are as follows:

1. *The iris disc.* Perforated transparent discs of ethyl cellulose are used to represent the iris and pupillary aperture. Ord-

inal part is possible. The button can be made ready for immediate selection and use in the wax form on presentation of the patient. In spite of its simplicity, it embodies such important features as the following:

(a) A predetermined average corneal curvature and depth of anterior chamber

Fig. 2 (Erpf, Wirtz, and Dietz). The die set.

nary artist's oil pigments selected for high quality and color permanency are applied on both sides of the transparent disc. This procedure is accomplished in such a manner that the background and collarette colors on the underside will be clearly discernible through the striations of the stroma color and markings painted on the obverse (fig. 1). This feature produces a true third-dimensional effect in the subsequent processing of the iris button.

2. *The iris button.* The stainless-steel die-set (fig. 2) contains sectional cavities which permit the processing of iris buttons of various sizes in plastic. The iris button comprised four essential features; namely, the painted iris disc, the jet-black pupil disc which is immediately behind the iris disc, the clear portion representing the anterior chamber and cornea, and the button stem.

The advantages of the button *per se* are obvious in that prefabrication of an es-

which can be subsequently adjusted to meet individual requirements. (b) A means of producing the all-important diffuse junction between the cornea and sclera and the opportunity of adjusting it to meet individual requirements. (c) A means of accurately selecting an iris of proper size and color without making allowance for the magnifying and intensifying effect of a subsequently placed clear plastic overlay (fig. 3).

3. *The impression technique.* Two alternate impression techniques are employed in developing a wax form which will determine the size and shape of the scleral portion of the artificial eye. The first, the simpler and more rapid of these, is a "compression-impression technique" which is indicated in all cases where the socket to be fitted is not of grossly abnormal configuration, such as might be caused by cicatrices, extensive loss of contents of the socket, or injury to the

Fig. 3 (Erpf, Wirtz, and Dietz). The iris button.

structures of the eyelids (fig. 4). The second method is termed the "injection-impression technique. It is more circuitous in nature and produces a no more effectively shaped prosthesis for the uncomplicated socket. It is advantageous, however, in those cases of extreme irregularity where retention of an adequate prosthesis constitutes a problem (fig. 5).

When the wax pattern obtained by the method of choice has been trimmed to the proper shape and size as indicated by anatomic and cosmetic requirements, the position of the iris button is marked. A circular recess is cut into the wax at this point and the iris button luted into place. The wax pattern is then tried in the socket, and such corrections are made as may be necessary to bring the iris into

final position and alignment. It is obvious that standard-shaped blanks of wax, placed in stock ready for reception of the iris button and refinement of fitting, may be employed to facilitate this step of the procedure.

4. *The mold.* A mold in two halves is then made of the wax pattern with its iris button. Upon separation, the wax and button are removed and the surfaces of the mold tin-foiled. The iris button is reinserted and the mold is ready for the packing and curing of the plastic which represents the sclera.

5. *The sclera.* The sclera plastic is a carefully blended mixture of finely ground, transparent methyl methacrylate

Fig. 4 (Erpf, Wirtz, and Dietz). The wax pattern.

Fig. 5 (Erpf, Wirtz, and Dietz). The injection impression.

with suitable opacifying agents and pigments. Several shades of sclera plastic are necessary to meet individual variations.

Assuming that the scleral portion has been processed around the iris button, the button stem is removed and the prosthesis is polished, care being taken to establish a proper blend at the corneoscleral junction. Provision for the simulation of an anatomically correct corneoscleral junction is one of the advantages of the technique described and is not ordinarily observed in all-plastic restorations of the more conventional types.

6. *The veining technique.* Red rayon threads are employed for this purpose

(fig. 6). The separated monofilaments are tacked in place with an alcohol-chloroform mixture. Very realistic ramifications are attained by adroit application. In order to effect the structureless and delicate capillary beds, red oil pigments are delicately and sparingly applied. Similarly, oil colors of appropriate shade may be applied to simulate the characteristic surface pigmentations found in the visible areas of the sclera. Pingueculae are reproduced if desired and also the reddish tinge found in the region of the nasal canthus where the margin on the prosthesis might be visible during extreme lateral excursions. The restoration is now ready for application of the clear layer which will represent the conjunctiva.

Fig. 6 (Erpf, Wirtz, and Dietz). The blood vessels of the sclera.

Fig. 7 (Erpf, Wirtz, and Dietz).
The finished prosthesis.

7. *Polishing and Fitting.* A final scratch-free polish is effected with suitable abrasive and buffing agents (fig. 7). The prosthesis, if carefully made, requires only minor adjustment upon insertion. Attention should be directed toward obtaining exact paralax. The contours of the cornea must be shaped to reflect high lights of identical number, size, and shape when compared to those of the eye on the

inspection reveal sockets that are clean and with good tissue tonus. Although this practice is not recommended, it is felt that it speaks well for factors of comfort and compatibility of synthetic resin in contact with tissue over long periods of time.

SUMMARY

The technique of fabricating plastic ar-

Fig. 8 (Erpf, Wirtz, and Dietz). Patient before and after insertion of prosthesis, Dibble General Hospital.

other side. This latter is extremely important, and the cosmetic success of the restoration greatly depends upon it.

The prosthesis is inserted (fig. 8) with a drop of mineral oil, and final instructions are given to the patient concerning proper care. Reference of the patient to the ophthalmologist is also desirable at this time.

It has been noted that many patients will wear prostheses for several weeks or months at a time without removal. Such well-fitted restorations when removed for

tificial eyes herewith described has satisfied the foregoing requirements. Its advantages are concerned principally with the inherent durability of the material used and the ease with which an optimum result may be realized. The method has been kept as simple as possible in order that no extraordinary artistic talent or technical skill would be required. The procedures involved are well within the capabilities of the average dental technician.

The design of the prosthesis is such

that it will permit fabrication in custom fashion with little more in the way of material and supply than those found in any prosthetic laboratory. The advantages of this feature, as, for instance, in a theater of operations, are obvious. On the other hand, where more elaborate facilities are available, stock production may be accomplished, if desired, without difficulty.

The basic synthetic resin, methylmethacrylate, is easily obtained, being a standard item used in the production of dental prostheses. It lends itself well to molding, coloring, and adjustment of size and shape after initial completion. Synthetic resin satisfies well the three factors important to the success of any prosthesis; namely, function, esthetics, and comfort.

CONCLUSION

1. A critical shortage of artificial eyes

developed as the result of wartime restrictions on imports of stock glass eyes and irides from Germany.

2. Military patients requiring artificial eyes were constituting a problem in hospitals in the United States and overseas because of this shortage.

3. A readily teachable technique was urgently required which would produce artificial eyes equal or superior to those made of glass.

4. An Army school for ophthalmoprosthetic technicians was established in the European Theater of Operations in 1943. This was followed by collaboration, intensification of research, and the organization of a second Army school in the United States.

5. By October, 1945, 30 Army installations had fabricated over 7,500 all-plastic artificial eyes in addition to those made by those installations originally established overseas.

METHACRYLIC RESIN IMPLANT FOR SUNKEN UPPER LID FOLLOWING ENUCLEATION*

H. SAUL SUGAR, M.D.

Chicago, Illinois

AND HARVEY J. FORESTNER, D.D.S.

St. Louis, Missouri

The program of plastic-artificial-eye fabrication in the Armed Forces of the United States has directed attention forcefully toward the problems of cosmetic defects after enucleation.

The most common defect that makes fitting a satisfactory prosthesis difficult is a sinking of the upper lid following enucleation. Attempts to use a larger prosthesis or to build up the prosthesis with a ridge on its anterior-superior face fail to achieve a satisfactory cosmetic result because they serve only to widen the palpebral fissure. This causes a staring expression and makes proper lid closure difficult. The implantation of fascia lata has thus far been the only satisfactory method of filling up the defect. The method has recently been greatly improved by Cutler.¹ However, this method requires a period of hospitalization for healing of the donor site. In addition, some fibrosis of the fascia takes place, with adhesions between itself and the orbicularis muscle and orbital septum between which it is placed. Removal, if required for any reason, is difficult, especially if the fascia was inserted some time previously. A more satisfactory method of correcting this defect was therefore sought. The criteria for such a method were considered to be: (1) satisfactory cosmetic improvement; (2) simplicity of technique; (3) a mini-

mal period of hospitalization; (4) a minimal period of postoperative reaction and interference with fabrication of the prosthesis.

These criteria were fulfilled by two methods, the first of which was discontinued in favor of the second after the results had been observed in three patients. Since this earlier procedure gave some insight into the cause of the sinking of the lid, it will be briefly described. It was observed that, especially in the extreme instances, the central portion of the depression of the upper lid with the palpebral fissure fully open had the most marked cosmetic defect. Since the level of this depression was behind the plane of the attachments of the orbicularis muscle, it could not be explained by contracture of this muscle. However, the backward pull of the levator, together with the absence of support for the upper portion of the upper lid, could account entirely for the sinking. It was assumed that, if a strip of orbicularis in the region of the sunken area were made taut, the depth of the depression could be decreased to the plane of the orbicularis attachments.

In each case an incision 24 mm. long was made in the skin of the upper lid in the superior orbito-palpebral sulcus. The skin was undermined in the portion above the incision to expose the orbicularis for a width of about 10 mm. The orbicularis was then split at the level of the skin incision and undermined upward. It was split again to form a band 5 mm. wide. This strip was cut at its center, and the

ends overlapped and sutured together to form a taut band. The split edges of the orbicularis were sutured together anterior to this strip. The skin was sutured subcuticularly with silk and a pressure bandage applied. In two of the three cases, the operation was performed on an out-patient basis, each of the two patients being off duty for 24 hours. The procedure was successful in decreasing the depth of the sulcus (fig. 1, case 1) but did not fill out the upper lid adequately. It then occurred to one of us (H. S. S.) that an implant of methyl methacrylate of proper shape could easily be fashioned and inserted underneath the orbicularis in the sunken lid. Impressions of both upper lids and brows were made on four patients with sunken upper lids after enucleation. The impressions were cast in stone, and a wax form was made to fill in the difference between the two. The form was cut off at the level of the superior orbitopalpebral sulcus so that the implant would not interfere with the function of the levator. The wax forms were found to be similar in each case. Plaster molds were then made from them.

The implants were made by combining one part of the liquid monomer form with three parts of the solid polymer

form of methyl methacrylate* to form a soft dough. Some of the implants were cured by placing the dough in the plaster molds at a temperature of 80°C. in a

press clamp producing 300 to 400 pounds of pressure per square inch, for 16 to 18

* Acralain acrylic no. 93 was the commercial substance used.

hours. The remaining implants were cured in boiling water for 1½ to 2 hours under the same conditions of pressure as the other implants. The finished solid products were then smoothed and polished (fig. 2). Because of slight variations in the size of the orbit in different individuals, the implants were made in varying sizes, 27 to 30 mm. in length and usually 5 to 8 mm. wide at the center. With several sizes of implant, each new

from pneumonia or were accidentally killed, none of the 31 remaining animals showed any abnormalities on gross necropsy examination at the end of the experimental period. The powder was found adherent either to the skin or abdominal wall, in a thinly encapsulated mass. No signs of irritation were present, nor were there abdominal adhesions in the animals subjected to the intraperitoneal administration.

patient could easily be fitted from the supply at hand. When necessary, they could be easily ground down to smaller size.

The tolerance of tissues toward methyl methacrylate has been the object of some investigation. The substance has the following chemical formula:

According to the findings in experiments by Haag² in 1939-40, the solid polymeric form of methyl methacrylate has no toxic effect on tissues. Haag placed fine granules of two commercial preparations of pigmented methyl-methacrylate polymer either subcutaneously or intraperitoneally in gelatin capsules in 60 mice. These were left for nine months. Although a number of animals were lost

The liquid monomer form of methyl methacrylate, unlike the polymer, has been found to be toxic in about the same order of toxicity as is acetone.² However, during the process of polymerization or curing, the monomer is changed to the polymeric form. In order to ensure using the most stable and fully cured resin, the curing process should take place at the temperature of boiling water, since physical studies by the manufacturers^{2a} indicate that the polymer is most stable and fully formed when cured at temperatures from approximately 210° to 240°F.

It is best to avoid using those preparations of methyl methacrylate which contain a plasticizer, since such resins are not so resistant to chemical change as is pure methyl methacrylate polymer.

The polymerized methyl-methacrylate resin is slowly soluble in esters and ke-

tones but is insoluble in water and alcohol. Because of its solubility in ketones, surgeons have been cautioned against the use of such an implant in cases of diabetes.³

Acrylic resins have been successfully used in other fields of surgery. Gurdjian,

capsule after enucleation, plastic spheres have been used by Wright,⁷ Cutler,⁸ Eggers,⁹ Berens and Rothbard,¹⁰ and others.

Five methyl-methacrylate implants, approximately 12 by 2 mm. in size, were inserted into the upper eyelids of three male albino rabbits through small inci-

Webster, and Brown⁴ used methyl methacrylate (plexiglass) for filling a skull defect and reported no deleterious action after 15 months. Walker, Taggart, and Lambros⁵ have also successfully used acrylic resin in the form of plates for filling skull defects; Brown,³ as implants for correcting nasal and chin deformities; Penhale,⁶ to correct facial deformities. Harmon,^{6a} used methyl methacrylate (plexiglass) for reconstruction of the femoral head. As an implant into Tenon's

sions in the skin and presumably part of the orbicularis. Two of the implants had been cured in boiling water, three had been treated by the longer process at a lower temperature. One of the latter was the pigmented type of methyl methacrylate resin often used in dentures. One of each of the three types of implants was allowed to remain for one month, after which the animals were killed. There was no visible difference in the tissue sections of any of the lids. The two remaining

implants were allowed to remain for two months, at the end of which period tissue sections showed no significant difference from those implanted for one month except for thinning of the connective tissue capsule. Grossly, the lids were soft, and the skin moved normally over the im-

dense fibrous tissue and lined by a flattened layer of fibroblasts and endothelial cells. A few scattered monocytes and lymphocytes are found in this granulation tissue. At the outer edge of the tract there are rare multinucleated giant cells of the foreign body type. A very few

plants. There was no gross evidence of inflammation. The implants were free and each was surrounded by a thin pale-pink membranous sac with a glistening inner surface. Microscopically, sections of the eyelid revealed* a "hollow tract bounded anteriorly by the subcutaneous connective tissue and fibers of the orbicularis muscle and posteriorly by a few fibers of the orbicularis muscle and the palpebral fascia. The tract is lined by chronic granulation tissue which, by compression and organization is being converted into

scattered lymphocytes and monocytes are found in the lamina propria of the conjunctiva" (fig. 3).

A biopsy specimen of the anterior wall of the implanted cavity was taken from one patient (case 7) during substitution of a longer implant, one month after insertion of the original implant. At the time of reoperation, the cavity had the same glistening pale-pink appearance described for the rabbit-lid implants. Microscopically, it had the same thin granulation tissue membrane around it that was found in the rabbit eyelids.

A total of 20 patients had methyl-

* Report by Major R. S. Aronson, pathologist.

methacrylate implants inserted, including the three patients on whom the original orbicularis-band procedure had been done.[†]

The implantation procedure is shown in figure 4. After the usual preoperative medication with morphine and scopolamine and preparation of the skin, a block type of anesthesia was employed (2-percent procaine-hydrochloride solution). A small quantity of procaine was injected through the skin over the supraorbital notch. The needle was carried down toward the inner canthus, and a small

its desired position on the upper lid (fig. 4B), about 1 mm. above the orbitopalpebral sulcus, with its temporal end lying just temporal to a vertical line drawn upward from the external canthus. The center of the implant then lay somewhat temporal to the center of the lid. An outline of the implant was drawn on the skin with a toothpick and a weak solution of gentian violet or mercurochrome (fig. 4C). A 15-mm. incision was made along the concave lower portion of the outline at its center (fig. 4D). The skin was held taut by an assistant who merely

Fig. 5 (Sugar and Forestner). Photographs of case 2, showing results of the use of methyl-methacrylate implant.

quantity of procaine injected at the inner angle of the upper lid (fig. 4A). The needle was then inserted at the outer end of the brow, and carried down to the outer angle of the upper lid, a small quantity of procaine being injected along its path. Then the needle was pulled back and inserted under the skin of the brow toward the supraorbital notch, a small quantity of procaine being injected as the needle was inserted. This type of anesthesia does not interfere with the proper placing of the implant by distortion of the tissues and does not interfere with the levator action. After about 5 to 10 minutes, anesthesia was complete. The patient wore his prosthesis during the procedure. The implant was sterilized in mercury-bichloride solution and placed in

pulled the brow upward with two fingers.

As soon as the skin incision had been completed, the orbicularis muscle was exposed (fig. 4E). By blunt dissection with a Stevens tenotomy scissors, the orbicularis was split along the same line as the skin incision and the orbicularis undermined in the area of the implant outline, forming two pockets, nasally and temporally (fig. 4F). The orbital septum lying beneath the orbicularis was easily recognized. One end of the implant was then inserted, and the skin and orbicularis were pulled over the other end (fig. 4G). The implant lay smoothly in its prepared location. The edges of the orbicularis muscle were sutured together with two mild chromic (4-0) catgut sutures (fig. 4H). A subcuticular silk suture in the skin completed the operation (figs. 4I and 4J). A pressure bandage was applied.

[†]Since this paper was submitted for publication, two more implants have been satisfactorily used, one in a girl aged 10 years.

Fig. 6 (Sugar and Forestner). Photographs of case 8, showing results of methyl-methacrylate implant.

Of the 20 patients operated upon, 11 were out patients. The pressure bandage was removed after 24 hours in a few cases and after two days in the others. Wearing of dark glasses was advised, solely for cosmetic reasons, until the skin suture would be removed, on the fourth day. The only complications were two instances of lid ecchymosis which cleared within 12 days. These occurred in one

patient who had the bandage removed in 24 hours and in one who had the bandage on for two days. In case 7, an implant larger than the one originally used was required. In three others, a smaller implant was substituted (cases 13, 14, and 20). In case 18, the lid was manipulated on the second day, permitting the implant to turn over easily. It was later removed, and the sac split and rebanded after

reinsertion of the implant. Healing was uneventful. Substitution was easily made through the original 15-mm. incision. No instance of infection or untoward reaction occurred. The implant could be felt easily through the skin. It became forcibly elevated. Definite cosmetic improvement was obtained in all cases.

A summary of the pertinent findings in the patients on whom implantations were made is shown in table 1. Two interesting facts were ascertained in these cases: (1) that a prolonged interval between enucleation and the original wearing of a prosthesis is not necessarily a cause of sinking of the upper lid; and (2) that the presence of an implant in Tenon's capsule does not prevent the occurrence of lid sinking. In 11 of the 20 patients, there was a time interval of less than one month between the enucleation and the first wearing of a prosthesis. Five of the 20 had had spheres implanted

into Tenon's capsule after the enucleation.

The cases have been followed for a period of two to four months and there have been no untoward results.* No difference was observed in the results from the implants made by the slow or rapid process. It is hoped that further followup may continue over a period of years in order to complete this preliminary study.

CONCLUSIONS

A simple method is described for introducing a methyl-methacrylate implant into the upper lid to fill out the sinking which sometimes occurs after enucleation of the eyeball. Experiments and a review of previous experience with this resin have been cited to indicate the lack of untoward results from this procedure.

58 East Washington Street (2)

* A follow-up by mail after six to eight months confirmed this conclusion.

CHARTING DIPLOPIA AND MUSCLE ACTION*

JOSEPH I. PASCAL, M.D.

New York

The action of each of the extraocular muscles is naturally determined by the manner of its attachments; that is, by its origin and insertion. Anyone who remembers and always visualizes the origin and insertion of each muscle will have no difficulty in determining its mode of action. However, teachers and writers of textbooks have always felt it necessary to devise some memory scheme which would help fix the pertinent facts in the student's mind. Many and varied schemes have been devised, but the inadequacy of most of these is probably best expressed by Sir J. Herbert Parsons, who, in his textbook, "Diseases of the eye," after explaining a mnemonic state, "... the student is even more liable to forget the mnemonic than his anatomy of the muscles."

The mnemonic which I employ is the old familiar benzene ring which every doctor knows from his early student days in chemistry. But before taking up the mnemonic it may be well to review very briefly the action of the extraocular muscles. The externi and the interni have simple actions. The right externus turns the right eye to the right (out), the right internus turns the right eye to the left (in). The left externus turns the left eye to the left (out) and the left internus turns the left eye to the right (in).

The vertically acting muscles have a threefold action, a primary action and two secondary actions. The primary action is up or down. The secondary actions are (a) a slight movement to right or left (in or out) and (b) a wheellike rotation or torsion—dextro-torsion when the upper part of the vertical meridian of the

cornea is turned to the right, or levo-torsion when the upper part of the vertical meridian is turned to the left. This may also be expressed as extorsion or intorsion according as the upper part of the vertical meridian is tilted toward the temple or towards the nose.

Figure 1 may be visualized as being directly behind or directly in front of the patient who faces us, so that right and left are the *patient's* right and left. The patient's eyes are directed straight forward; that is, they are in the primary position. The diagram is set in the mid-line, and the center of the ring, C, may be thought of as corresponding to the patient's bivisual line or to the projection of his nose. The rectus muscles are placed first, the muscles of the right eye on the right side of the ring and the muscles of the left eye on the left side of the ring.

At the right upper limb are placed the right superior rectus (R. S. R.) at the right middle limb, the right externus on the outside, the right internus on the inside, and at the right lower limb the right inferior rectus (R. Inf. R.). Similarly, on the left side of the ring, at the left upper limb the left superior rectus (L. S. R.), at the left middle limb, outside the left externus, inside the left internus, at the left lower limb the left inferior rectus (L. Inf. R.). Once the rectus muscles are set down at the places their names indicate, the position of the obliques is found from the general rule that the oblique muscles are placed at their *complete opposites*. Thus the right superior oblique is placed at the limb of the left inferior rectus, the right inferior oblique at the limb of the left superior rectus, the left superior oblique at the limb of the

* Presented before the New York Society for Clinical Ophthalmology, March 4, 1946.

Figs. 1 and 2 (Pascal). Mnemonics for placing the extraocular muscles and the function.

Figs. 3 and 4. Method of transferring diplopia data from the benzene-ring mnemonic to the 9-square chart.

Fig. 5. Mnemonic as in figures 1 and 2 with additional data for registering diplopia from paralysis of horizontal rectus muscles.

right inferior rectus, and the left inferior oblique at the limb of the right superior rectus.

The action of each muscle is now seen from the corresponding limb of the ring as follows: The R. S. R. (at the right upper limb) turns the right eye up, its principal action, a little to the left or in (the midpoint of the limb is shifted slightly to the left), and produces levotorsion or intorsion (secondary actions). The upper part of the vertical meridian of the right cornea is tilted to the left, corresponding to the slant of the right upper limb. The right externus and the right internus move the eye in the direction indicated by their positions, the right externus to the right (outward), the right internus to the left (inward). The right inferior rectus at the right lower limb moves the right eye down, its principal action, a little to the left or in (midpoint of limb is shifted to left), and produces dextro-torsion or extorsion (secondary actions). The upper part of the right cornea, like the upper part of this limb, is tilted to the right.

Similarly, the left superior rectus (at the left upper limb) turns the left eye up, its principal action, a little to the right or in (midpoint of limb is shifted slightly to right), and produces dextro-torsion, intorsion (secondary actions). The upper part of the cornea is tilted to the right, as is the case with the corresponding limb. The left externus and left internus move the left eye as indicated by their position. The left inferior rectus (at the left lower limb) turns the left eye down, its principal action, a little to the right or in, and produces levo-torsion or extorsion (secondary actions). The upper part of the vertical meridian of the left cornea is tilted to the left, as indicated by the slant of the corresponding limb.

The right superior oblique (at the limb of the left inferior rectus) moves the

right eye down, its principal action, a little to the right or out (midpoint of limb is shifted to right), and produces levo-torsion or intorsion (secondary actions). The upper part of the right cornea is tilted to the left, as the corresponding limb. The right inferior oblique (at the limb of the left superior rectus) turns the right eye up, its principal action, a little to the right or out, and produces dextro-torsion or extorsion (secondary actions), all of which actions are indicated in the corresponding limb. The left superior oblique (at the limb of the right inferior rectus) turns the left eye down, its principal action, a little to the left (out), and produces dextro-torsion or intorsion, as indicated by the corresponding limb. The left inferior oblique (at the limb of the right superior rectus) turns the left eye up, its principal action, a little to the left (out), and produces levo-torsion (extorsion), as indicated by the corresponding limb.

Visualizing the ring does more than help one remember the complete action of each of the extraocular muscles. After using the mnemonic several times one learns to "project" the ring, so to say, onto the eyes and to visualize directly the action of the muscles, especially the three-fold action of the vertical muscles, by the position, shift, and slant of the corresponding limb.

The "ring" also shows the greatest field of action of the various muscles. The principal action of the vertical muscles on the right side of the ring is most marked when the eyes are turned to the right as the starting position. Thus the up-and-down effect on the right eye by the right superior rectus and the right inferior rectus is most marked when the right eye is turned to the right (out). Similarly, the up-and-down effect on the left eye by the left inferior oblique and the left superior oblique is most marked

when the left eye is turned to the right (in). When the principal action is most marked, the secondary actions are least marked. Therefore, when the eyes are turned to the right, the secondary actions of the muscles situated on the right side of the ring are least marked. When the eyes are turned the other way—that is, to the left—conditions are just reversed, as would be expected. The principal (up-and-down) action of the muscles situated on the right side of the ring is now less marked, whereas the secondary actions are more marked.

Similarly, the principal action of the vertical muscles on the *left* side of the ring is most marked when the eyes are turned to the *left*. Their secondary actions are then least marked. When the eyes are turned the other way—that is, to the right—the principal action of these muscles is least marked and their secondary action most marked.

For those interested only in remembering the action of each of the extraocular muscles, figure 1 is adequate. But for those interested in the action of the associated muscles in binocular vision and for charting the type and position of the false image in diplopia, figure 2 is preferable.

The benzene ring is drawn and the muscles placed in pairs, each with its associate as follows: Beginning at the right upper corner are placed the right superior rectus (as indicated by name) and, immediately below, the name of its associate muscle, which is its complete opposite; namely, the left inferior oblique. At the right middle limb outside, are placed the right externus (as indicated by name) and, immediately below, the name of its associate, its complete opposite, therefore the left internus. At the right lower corner, are placed the right inferior rectus (as indicated by the name) and, immediately below, its associate, its complete

opposite; namely, the left superior oblique.

At the left upper corner are placed the left superior rectus (as indicated by the name) and, immediately below, its associate (its complete opposite); namely, the right inferior oblique. At the left middle limb outside are placed the left externus (as indicated by name) and, immediately below, its associate (its complete opposite); namely, the right internus. At the left lower corner are placed the left inferior rectus (as indicated by name) and, immediately below, its associate (its complete opposite); namely, the right superior oblique.

This ring is a complete mnemonic and the only one necessary to remember for all muscle work. It shows the most characteristic field of action of each muscle and of each group of associated muscles. For the right externus and left internus it is to the right, as shown by the right middle limb. For the left externus and right internus it is to the left as shown by the left middle limb. The vertical movement is most marked at the corner indicated. Thus for the R. S. R. and the L. Inf. O. the greatest vertical movement (up) is at the right upper corner; that is, when looking up and to the right. For the L. S. R. and the R. Inf. O. the greatest vertical movement (up) is at the left upper corner; that is, when looking up and to the left. For the R. Inf. R. and the L. S. O. the greatest vertical movement (down) is at the right lower corner; that is, when looking down and to the right. And for the L. Inf. R. and the R. S. O. the greatest vertical movement (down) is at the left lower corner; that is, when looking down and to the left.

The secondary actions, especially the torsion, are most marked in the opposite corner: that is, for the R. S. R. and the L. Inf. O. the greatest torsion is at the left upper corner; for the L. S. R. and

the R. Inf. O. the greatest torsion is at the right upper corner. For the R. Inf. R. and the L. S. O. the greatest torsion is at the left lower corner, and for the L. Inf. R. and the R. S. O. the greatest torsion is at the right lower corner. All this simplifies the statement that the greatest up-and-down movement is at the corner marked up or down, whereas the greatest torsional movement is at the opposite corner.

The diplopia resulting from a paretic muscle is easily charted from the ring (fig. 2) because, to paraphrase Maddox, "the false image is what the normal muscle *does*." The "false image," of course, belongs to the eye with the paretic muscle. In paralysis of the right externus or its associate the left internus, the false image is to the right (out), and is farthest from C, when the gaze is in the direction of the right middle limb. The separation of the images diminishes when the gaze is in the other direction; that is, toward the left middle limb. In paralysis of the left externus or its associate the right internus, the false image is to the left (out), and is farthest from C when the gaze is in the direction of the left middle limb. The separation of the images diminishes when the gaze is in the other direction; that is, toward the right middle limb.

In paralysis of the R. S. R. or L. Inf. O., the false image is higher, most marked in the right upper corner at the right upper limb and is tilted to the left, the tilt becoming more marked when the gaze is toward the opposite (left upper) corner. In paralysis of the L. S. R. or R. Inf. O., the false image is higher, most marked in the left upper corner, at the left upper limb, and is tilted to the right, the tilt increasing on looking to the opposite (right upper) corner.

In paralysis of the R. Inf. R. or L. S. O. the false image is lower, most marked in the right lower corner, at the right

lower limb, and is tilted to the right, the tilt increasing when the gaze is toward the opposite (left lower) corner. In paralysis of the L. Inf. R. or R. S. O., the false image is lower, most marked in the left lower corner at the left lower limb, and is tilted to the left, the tilt increasing when the gaze is to the opposite (right lower) corner.

The slight horizontal displacement of the false image in paralysis of a vertically acting muscle may be neglected, for it is of little value and is sometimes confusing, but it, too, is implicit in the figure.

While the "ring" is the basic figure for charting the diplopia, it is desirable to transfer the information derived from the ring to the 9-square diplopia chart for more detail. Let the image of the right eye be designated by a line with a little circle on top (round head, right eye), and the image of the left eye by a simple line. In a case of paralysis of the R. S. R., the false (right-eye) image is shown by the right upper limb of the ring. The true image, fixated by the left eye is recorded in the right upper square, figure 3, where the vertical separation will be most marked; the false image is shown as higher, to the left, and levo-torted, as indicated by the right upper limb. At the opposite corner, the left upper square, is placed the false image so that the vertical separation is less, the torsion greater.

Or, in a case of paralysis of the R. S. O., the false (right-eye) image is shown by the left lower limb. Record the true image, fixated by the left eye, in the left lower square, figure 3, where the vertical separation will be most marked; the false image lower, to the right and levo-torted, as indicated by the left lower limb. At the opposite corner, the right lower square, is placed the false image, so that the vertical separation is less, the torsion more.

The false image resulting from paral-

ysis of any other muscle can likewise be "seen" on the ring and transferred for greater detail to the 9-square chart.

The 9-square diplopia chart can also be used, and to some this seems especially convenient, by starting from the middle square, corresponding to the primary position of the eyes. Paralysis of any of the muscles at the upper limbs of the ring will cause diplopia, principally in the upper field, and paralysis of the muscles placed at the lower limbs of the ring, principally in the lower field. Thus, for example, in paralysis of the L. S. R. the false image corresponds to the left upper limb. Transferred to the 9-square chart and starting from the upper middle square, the false (left-eye) image relative to the fixated (right-eye) image will be higher, to the right, and dextro-torted, figure 4. In the left upper corner (principal field of action of the affected muscle), the vertical separation will be more marked, the torsion less. In the opposite corner (right upper square) the vertical separation will be less marked, the torsion more. Lower part of figure 4 shows the false image transferred from the ring in paralysis of L. S. O. When the three upper or the three lower squares are filled in, the diplopia in the middle squares can be filled in if a complete textbook picture is desired. Figures 3 and 4 are considered as they face the patient, as if the examiner were facing the patient from behind the chart. Right and left are according to the patient's right and left.

Those interested in some refinements in charting diplopia may memorize figure 5 instead of figure 2 as a complete mnemonic. It is an amplification of figure 2 and gives additional information about the diplopia resulting from paralysis of the horizontal rectus muscles. It consists of the main benzene ring, as in figure 2,

with the beginnings of another ring on each side. It shows everything figure 2 shows with this additional information:

The right upper extension shows that in paralysis of the right externus or left internus the false image tilts to the right when looking up and to the right. The right lower extension shows that under similar conditions the false image tilts to the left when looking down and to the right.

Similarly, the upper and lower extension on the left shows that in paralysis of the left externus or right internus the false image tilts to the left on looking up and left, and tilts to the right on looking down and left. The torsion is always the same as the slant of the corresponding limb in the direction indicated.

The benzene-ring mnemonic, can also be used for remembering muscle action by referring the action to the muscles of one's own eyes. Exactly the same method is used, but "right" and "left" of the ring must be reversed. Similarly, for charting the false image, the ring and the chart may be considered as facing the patient and also the examiner. Here, too, everything works out exactly the same, but "right" and "left" must be reversed. Some textbooks use one method, some the other, but either method is compatible with the ring mnemonic.

A mnemonic is merely an aid to visualizing muscle action. When used with intelligence, this mnemonic has been found useful not only for remembering the action of the individual muscles and for textbook charting of the false image when the paralyzed muscle is given, but also for helping to locate the paralyzed muscle from the position and tilt of the false image.

NOTES, CASES, INSTRUMENTS

STREPTOMYCIN TREATMENT OF A CORNEAL ABSCESS CAUSED BY *ESCHERICHIA* *COLI**

WILLIAM C. OWENS, M.D.
Baltimore, Maryland

There has been an intensive search for a chemotherapeutic agent active against organisms resistant to the sulfonamides and penicillin. Recent experiments show that streptomycin, a new antibiotic, partially fulfills this need. Waksman and his associates isolated this antibiotic from the filtrate of a meat-extract culture of *Actinomyces griseus*.¹ Streptomycin is bacteriostatic against certain gram-negative as well as gram-positive organisms. This activity has been demonstrated *in vitro*, in animals, and in preliminary experiments in man. Among the organisms against which it appears to be effective are *Escherichia coli*, *Mycobacterium tuberculosis*, *Eberthella typhosa*, *Brucella abortus*, *Pasturella tularensis*, *Hemophilus influenzae*, and *Proteus vulgaris*. Preliminary reports have shown no significant toxicity when streptomycin is administered orally, subcutaneously, or intravenously at therapeutic levels.²

A small amount of streptomycin became available during the treatment of an apparently intractable case of *Escherichia coli* abscess of the cornea. Its use was followed by dramatic improvement.

CASE REPORT

W. T., a colored man, aged 54 years, was first admitted to the Ophthalmological Service on June 26, 1945, complaining of poor vision, lacrimation, photophobia,

and pain in his right eye. He stated that three weeks before admission a "piece of gravel" had lodged on the cornea of his right eye. In spite of local and systemic treatment by his family doctor, a corneal ulcer developed. Prior to the present illness, the patient had had no ocular complaints.

Examination. The routine laboratory and general physical examinations were negative except for slight peripheral arteriosclerosis. The blood pressure was 170/88, the blood sugar 89 mg. percent, and the serologic tests for syphilis were negative.

Right Eye. There was marked edema of both lids with a spastic entropion of the lower lid. Slight mucopurulent discharge was present. The palpebral and bulbar conjunctivas were markedly hyperemic, and the pericorneal vessels were intensely injected. In the center of the cornea was an opaque area 6 to 7 mm. in diameter, extending throughout the entire corneal stroma. The surface was irregularly excavated, with ragged overhanging edges. This entire area stained heavily with fluorescein. The surrounding rim of cornea was slightly infiltrated in the superficial layers of the stroma. The anterior chamber was of normal depth with a hypopyon in the lower third. The aqueous ray was moderately positive. The iris and lens could be seen only with difficulty; the pupil appeared well dilated and the lens was grossly clear. Tension was slightly elevated to fingers. There was no red reflex. Vision was limited to light perception with good projection.

A culture of the corneal abscess taken on admission showed a heavy growth of *Escherichia coli*.

Left Eye. External, ophthalmoscopic and slitlamp examinations revealed no

* From the Wilmer Ophthalmological Institute of The Johns Hopkins University and Hospital, Baltimore.

abnormalities. Corrected vision was 20/20, and visual fields were normal.

Therapy and Course. The patient was given 10,000 units of penicillin intramuscularly every three hours during the day and night, and 1 gm. of sulfamerazine orally twice a day. Local treatment consisted of the instillation of one drop of a 10-percent solution of argyrol followed by irrigation with boric-acid solution every four hours. Penicillin ointment (500 units per cubic centimeter) was

taining 500 standard units of streptomycin per cubic centimeter were instilled into the right eye every hour during the day and night. In 48 hours, there was marked improvement. The cornea had begun to clear in the periphery and the abscess was more shallow. On the fifteenth hospital day, the systemic use of penicillin and sulfamerazine was discontinued. At the same time, through a mistake in dilution, the concentration of the streptomycin instilled into the conjunctival sac was in-

Fig. 1 (Owens). Right eye before treatment with streptomycin. Fig. 2, The same eye 19 days after treatment with streptomycin.

placed into the conjunctival sac following each irrigation. In addition one drop of a 1-percent solution of atropine sulfate was instilled twice a day. Nevertheless, the abscess continued to progress rapidly. On the fifth hospital day, two subconjunctival injections of 0.25 c.c. of a solution containing 10,000 units of penicillin per cubic centimeter were given six hours apart. These also had no effect. In addition to the necrotic corneal abscess, a complete posterior synechia and a mature cataract had developed. The patient had lost light perception in this eye, and it was thought enucleation was inevitable.

On the seventh hospital day, a small amount of streptomycin became available.* The local use of penicillin was discontinued. Two drops of a solution con-

creased to 10,000 standard units per cubic centimeter. This concentration was used for one week after which the original dilution containing 500 standard units per cubic centimeters was used again. During this period of increased dosage, the eye continued to improve steadily. The local use of streptomycin was continued for a total of 23 days. At that time the corneal abscess had healed and was replaced by an epithelized leukoma.

On August 14, 1945, the patient was discharged from the hospital. The lids were normal. The bulbar and palpebral conjunctivas showed minimal hyperemia. A central leukoma, 5 mm. in diameter,

* The streptomycin was generously supplied by Merck and Company, Inc., Rahway, New Jersey.

extended through the entire thickness of the cornea. Its surface was completely epithelized and did not stain with fluorescein. There was a bullous area 1 mm. in diameter at the lower nasal margin of the leukoma. The anterior chamber was deep. The aqueous ray was negative and there were no keratitic precipitates. A complete posterior synechia bound the

iris to a mature cataract. The ocular tension was normal to fingers. There was no light perception.

CONCLUSION

A severe corneal abscess caused by *Escherichia coli* responded to the local use of streptomycin.

RECONSTRUCTION OF THE FLOOR OF THE ORBIT*

REPORT OF A CASE

ISADORE GIVNER, M.D.

New York

In a case of severe comminution of a malar bone associated with the floor of the orbit, the level of the eyeball may be displaced downward and the attachment of the inferior oblique muscle disturbed. Pfeiffer¹ reported 53 cases of traumatic enophthalmos. He related the mechanism of the internal orbital fracture responsible for the posterior displacement of the eye to be as follows:

"The posterior convex position of the floor bulges upward back of the eyeball in a position to receive most of the force transmitted by the eye. The floor is very thin, similar in weight to the lamina papyracea and is braced but slightly by the infra-orbital groove or canal. In cases of more severe enophthalmos, the posterior portion is fractured and in cases of more severe displacement the entire floor is broken through."

Central vision was destroyed in only 4 of 24 cases. Treatment is usually deferred from three to six months until residual inflammatory thickening and induration of soft tissue have disappeared. Wheeler² suggested the use of fascia lata gently tucked into the cavity. It should be completely covered so that it will not be exposed to air. Skin edges are prepared for the halving union and brought together by 000 chromic catgut. Converse³ suggested bone as employed by Gillies. He stated that there is clinical evidence of reossification and survival when these are placed against bone subperiosteally. Spaeth⁴ utilized cartilage either mortized or cut to shape. He emphasized the advantage of preserving

perichondrium if the cartilage is mortized.

The following report is made of an extreme case which was improved with cartilage cut to shape and preserved from cadavers. Cadaver cartilage is removed under strictly aseptic conditions from individuals who have no communicable disease. The cartilage is cleansed and the perichondrium taken off. It is kept continuously in a refrigerator in a solution of normal saline (four parts) and solution of merthiolate (one part). The solution is changed weekly. Culture of the solution must be made each time before use.

CASE REPORT

C. P., a white woman, aged 43 years, was admitted to the Beth David Hospital on November 29, 1944, after having jumped from a sixth floor with suicidal intention. In addition to the injury of the left orbit, the patient had fractures of the frontal bone, the left zygoma, the nasal bones, mandible, head of the right humerus, transverse processes of the third and fourth lumbar vertebrae, pubis, neck of the left femur, and the left tibia and fibula.

Her past history was irrelevant except for the fact that a diagnosis of involutional melancholia had been made previously. Ophthalmologic examination on January 12, 1945, showed the lower border of the left orbit to be 10 mm. lower than that of the right orbit.

With the exophthalmometer, measurements of 14 mm., in the right eye, and of 5 mm., on the left eye were found. The palpebral aperture of the right eye measured 10 mm.; that of the left eye, 8 mm. In the left palpebral aperture, one could see only 1 mm. of the cornea above the lower lid, for the rest of the eyeball was pushed down into the antrum (fig. 1). There was a marked paresis of the left

* From the Ophthalmological Service of Beth David Hospital.

superior rectus and inferior oblique muscles. Hypotropia measured 60 P.D.

On February 16th, after her more serious fractures had been cared for, a reconstruction of the floor of the orbit was undertaken.

(1) A skin incision was made along the lower border of the left orbit down to the periosteum. The latter was incised, and the orbital content elevated subperiosteally.

(2) The elevator was carried back for a distance of 12 mm. from the orbital rim.

Fig. 1 (Givner). Patient reported by Pfeiffer* showing severe enophthalmos of somewhat less severity than was present in the case herewith reported.

A piece of costal cartilage was then shaped to fit the defect, arching upward and elevating the eye 12 mm. Bleeding was controlled (fig. 2).

(3) The periosteum was reunited with chromic catgut, and the orbicularis reinforced with the same type of suture. The skin was closed with interrupted dermal sutures, and a pressure bandage applied. The patient was put on sulfadiazene systemically. The first dressing was done after five days. The first postoperative result showed the globe to have returned to the palpebral aperture, but with a noticeable hypotropia (fig. 3).

The status of the patient at the time of writing this is: At 105 mm., the right eye

* Acknowledgment is made to Dr. R. L. Pfeiffer and to the Archives of Ophthalmology for permission to use this photograph. The latter appeared on page 724. See reference 1.

Fig. 2 (Givner). Implanted cartilage inked in to show approximate position.

measures 14 mm.; the left eye, 8 mm. Vision is: R.E., with a +0.50D. cyl. ax. 180°, 20/20; left eye, with a plano, 20/20. The remainder of the examination, including media, tension, fields, and fundi, shows nothing abnormal in either eye.

In making a survey of materials used for cranioplasty, one finds such substances as animal bone, celluloid, aluminum, gold, silver plate, platinum, decalcified bone and buttons of bone. More recently, use has been made of bone chips and whole blood. Alloplastic substances such as vitalium have received attention, but plates of this material are difficult to mold and get into shape. In September,

Fig. 3 (Givner). Patient as pictured nine months after the operation.

1942, Col. R. G. Spurling (MC) performed the first cranioplasty with tantalum implant, in the Walter Reed Hospital. This material is valuable because: (1) It is relatively inert in tissues, although a thin, translucent, connective-tissue capsule does appear about this element when used in the form of tantalum foil. (2) It is malleable, without loss of strength. Flat sheets, .015 and .020 in. thick and 6 in. square, are now available. Certain resins such as plexiglass (methacrylate) appear to be entirely inert in tissues and may yet prove valuable.

CONCLUSION

Interest of this case lies in the fact that:

1. It is an addition to the literature describing how good visual function was preserved in spite of marked traumatic enophthalmos.

2. The perichondrium is not absolutely necessary for a successful subperiosteal implant.

3. A periosteal implant may be taken from cadavers and put in as an arch to elevate the globe without interfering with intraocular pressure or function.

ESSENTIAL XANTHOMATOSIS WITH HYPERCHOLESTEREMIA

DR. ALLEN DELEWETT said that essential xanthomatosis is one of the lipodystrophies or disorders of fat metabolism. The most widely supported theory concerning the etiology of these derangements is that there is an intracellular disturbance of lipid metabolism, perhaps due to a faulty enzymatic system, that results in the accumulation of large quantities of fatty substances within the cell. These fat-laden cells are called foam cells and their presence is the characteristic feature of the lipodystrophies. A family of nine was described, all of whom have essential xanthomatosis with hypercholesteremia and four of whom, aged 10, 11, 14, and 51 years have an arcus senilis. In 27 percent of the total series of 48 cases of essential xanthomatosis with hypercholesteremia, there was an arcus senilis; one half of these patients were younger than 40 years. It is probable that histologic examination of the arcus in such cases would reveal collections of cholesterol-laden cells in the corneal layers. The cornea is one of the more frequently involved sites of lipid infiltration in this disease.

OCULAR CHANGES IN RATS ON AMINO-ACID (TRYPTOPHANE) DEFICIENT DIETS

DRS. ARMANDO FERRARO and LEON L. ROIZIN have been studying the effects of amino-acid-deficient diets upon the growth, development, and morphology of

the various body tissues, organs, endocrine glands, and nervous system in rats, for the past three years.

In this preliminary report, Dr. Roizin limited himself to describing and discussing only the ocular involvement in rats on experimental tryptophane-deficient diets.

Material and Method. A total of 89 young (45-55 gm.), adult (100-120 gm.), and older (200 gm.) albino rats, belonging to the same strain, litter, and sex (male), was used in these experiments.

The animals were separated into four groups: The first group was fed on a tryptophane-deficient diet as suggested by Albanese and co-workers with the exception that the vitamin mixture was administered according to the method of Riess and Block. The other three groups of rats were used as controls.

Experimental findings. Most of the animals on tryptophane-deficient diet disclosed, in various degrees, arrest of growth, loss of body weight, changes of the general appearance, alterations of the fur (structural changes, rarefaction, and alopecia), and atrophy of the gonads. In addition, ocular involvement of various degrees of intensity was noticed, particularly in the very young animals and the group of rats weighing 100-120 gm. at the beginning of the experiment. These ocular involvements may be described as follows:

1. Spectacle eyes with very marked edema and congestion of the eyelids and conjunctiva, with presence of catarrhal and mucous secretion, causing at times adherence and complete occlusion of the eyelids, unless treated with medicinal or saline solutions. These changes appeared from 4 to 6 weeks after the beginning of the experiments.

2. Various degrees of cataractous changes of the lens, particularly in the more developed animals, appearing within 5 to 11 weeks from the beginning of the experiment. In addition, a large number of animals revealed very marked vascularization (hyperemia and hyperplasia) of the cornea, which was not limited to only certain parts, but involved the entire corneal circumference.

During the animals' lifetime, ophthalmologic examination of their lenses was conducted by Dr. Givner, who noticed various degrees and different types of opacities.

Histologic investigation disclosed various degrees and different types of opacities and structural changes of the lens in a large number of animals on tryptophane-deficient diet. At times the morphologic alterations were distributed in layers, lamellae, or concentric formations; at others, complete disorganization or disruption of the histologic structure was observed.

Clinical observations indicate that certain of these ocular manifestations—such as, spectacle eyes and involvement of the conjunctiva—are definitely reversible. To what extent and degree the involvement of the lens is also reversible the authors do not know at the present time, because their histologic data are not complete. However, some of the results in certain animals are very encouraging as far as improvement could be gauged by external appearance and ophthalmologic examinations.

Discussion. Dr. Isidore Givner said that tryptophane corneal vascularization has been said to be characteristically localized in the nasal and temporal portions of the cornea. The animals herein reported showed vascularization in all zones of the cornea. After tryptophane administration the corneal vessels narrowed but were still present on slitlamp study.

Tryptophane must be supplied in the diet, since the rat cannot synthesize it, at least in adequate amounts. A question that presents itself is: How applicable is the deficiency diet to human beings? In the proteolysis of lenticular proteins, tryptophane has been found in addition to 14 other amino acids. If we consider that the average time in rats for the development of tryptophane cataract is two months and that their life expectancy is three to four years, a comparable time in humans would be about three years on a tryptophane-deficient diet. In spite of the fact that amino acids are necessary for the elaboration of lenticular proteins, according to our present state of knowledge, and considering the ubiquity of this amino acid, Dr. Givner does not believe one could categorically attribute cataract in the human to this factor.

Slitlamp examination at regular intervals indicates a certain pattern in the method of development of the cataract in the rat. A feathery opacity with leaflike margins developed in the posterior subcapsular cortex. The suture lines were clearly visible and gaped slightly. Medium-sized vacuoles were visible in the suture lines and later under the anterior capsule. Later spokelike opacities appeared in the anterior cortex, followed by perinuclear opacities. The latter gave a milky appearance to the lens; and the nucleus became more opaque. The perinuclear zone widened. In looking at the lens through the dilated pupil, with room light at first, the pupil appeared grayish, but in the final state pearly white. In the gray stage, a red reflex was obtained with the ophthalmoscope but was obliterated when the pupil was pearly white.

After the rats have been given tryptophane, the pearly white opacities became less dense, so that the red reflex was obtained. There has been insufficient time to see how far this reversible change will

continue. If the change is one of fluid imbibition, it is reversible; if there is coagulation it is irreversible. About 65 per cent of the whole lens is composed of water. Part is free and part bound. It would seem in the development of cataract that the initial increase in water content is essentially an osmotic effect, owing to the high pressure generated by the fragmentation of large protein molecules into the smaller osmotically active derivatives of autolysis; this water remains free, accumulating beneath the capsule, and gathering in vacuoles and in fissures in the sutures. Such an accumulation impairs the transparency of the tissue, a tendency increased by the lessened imbibitional power of the lenticular proteins, so that while the free water increases, the bound water is lessened. Some of this state of edema certainly resolves, and optical transparency returns. The difficulties of observing microscopic changes corresponding to opacities seen in living animals in experimental work are well known, yet where we have reported vacuolization, the histo-pathologic specimen has at least shown this change. When we consider that the only cells that show regenerative activity are of the subcapsular epithelium, the explanation for lens clearing thus far will therefore have to be on a basis of water transference.

Finally, from a clinical point of view, no objection can be made to accept the recommendation that persons past the middle age and particularly those showing vacuoles, lamella separation, and water clefts be placed upon a well-balanced diet supplemented with vitamins, particularly vitamin C and vitamin-B complex.

As new findings of the physicochemical processes in the lens are uncovered, it is quite possible that medical treatment of early cataract will play a more prominent role.

ROUND-TABLE DISCUSSION ON NUTRITION

Panel comprised by Drs. Norman Jolliffe, H. D. Kruse, Harry Solomon, and Arthur Yudkin

Question. What vitamins can be synthesized in the human body and in what way can this be effected?

DR. NORMAN JOLLIFFE. The chief example is vitamin K. Others have been shown experimentally by deficiency symptoms as a result of egg-white injury; on record is a human case due to a self-imposed diet of sherry and two eggs. A group of workers experimentally demonstrated in the human gut the synthesis of thiamin and riboflavin; although subsequently the diet used was found to contain thiamin, the possible synthesis of riboflavin by bacteria in the gut is still valid.

Question. What ocular expressions of vitamin-B deficiency have you found in human subjects in New York City?

DR. F. H. KRUSE. The symptoms of B₂ deficiency, as seen in New York, are photophobia, lacrimation, and ocular fatigue; the tissue changes are vascular engorgement at the limbus and invasion of the cornea. The cases are usually chronic, although some are subacute; acute cases, such as were found in the Indians of Northern Manitoba, are not seen. Recession of the fully developed acute form may take place in a matter of days, whereas the chronic variety may not clear up for years. The symptoms disappear before the tissue changes.

Question. Discuss the question of increased viral antibodies in thiamine deficiency.

DR. SOLOMON. Mice experimentally infected with the virus for poliomyelitis were found to have a longer incubation period for the disease and a lower frequency of paralysis when on a diet de-

ficient in thiamin as compared to control groups on adequate diets. Malnutrition is not a factor, as the rates are essentially the same on starvation and adequate diets.

Question. Have you ever seen cataract development influenced by nutritional factors? What irrefutable evidence can you present to support your conclusions?

DR. A. M. YUDKIN. The question as it now stands cannot be answered by yes or no. The etiology or the mechanism of cataractous formation is still unknown. The causes of cataract are many and various, and it may be that they affect the transparency of the lens in many different ways. That general metabolic disturbances have an influence in the determination of cataract has always seemed obvious, both on account of the bilaterality of the condition and because of its tendency to develop in conditions of ill health.

There is no reason to suppose that there is only one cause or one principal cause operating in all cases.

Two definite changes in the structure of the lens produce diminished vision. One change is swelling of the tissue; the other, the formation of visible lenticular opacities. By means of the slitlamp the swelling of the lens tissue is found to be, in many instances, an invasion of the subcapsular tissue and that of the adult nucleus with fluid.

Although a considerable amount of information has been accumulated concerning the chemical changes that take place in the formation of cataracts, no definite clue to the etiology of the abnormal fluid in the tissue has been discovered.

It is a fact that the second condition, represented by the formation of opacities in the lens, is a "breaking down" of the structure of the normal lens tissue. This condition of the lens is not reversible from opacity to transparency. The first-named change is probably essentially one

of hydrolysis, whereas the second is a process of coagulation. It is apparent from analyzing the numerous papers on nonsurgical treatment of cataract that several prominent ophthalmologists have been able to check the progress of incipient stages of cataract either by using local medication and irritation, or by removing foci of infection and building up the body with proper food, or by a combination of local and general treatment. There is no irrefutable evidence that nutritional factors alone can produce a reversible condition in cataract formation if there is a derangement and destruction of the normal lens tissue. However, a review of some of the cases wherein lens changes have been repaired, or a reversible action has taken place by treatment with a well-balanced diet supplemented with vitamin-B complex and vitamin C, reveals that these cases belong to the first group of lens changes, namely, swelling of the lens tissue. Cataracts have been produced experimentally by depriving the laboratory animal of riboflavin or tryptophane and by substituting lactose or galactose in the diet for dextrose. If the diet was corrected before definite opacities were formed in the lens, the lens tissue did not develop into mature cataracts. When the lens was altered so that matured cataracts were formed, the improved diet had no reversible effect on the lens. Once coagulation invades the lens tissue, a reversible or regressive process does not take place with restoration of a well-balanced diet plus any of the known vitamins.

Question. What are conditioning factors and how may they influence the nutritive status?

DR. JOLLIFFE. They are the factors associated with disease, growth, or ordinary living conditions, such as sunlight, which will increase the requirements or the excretion or destruction of nutrients or fac-

tors that will impair their absorption for utilization. Increase of the bodily metabolism by hyperthyroidism, physical exertion, or restlessness over a period of time will raise the amount of vitamins required. An example of a factor which may destroy certain of the nutrients is the alkaline therapy, used in cases of gastrointestinal disease, that can destroy a large part of the thiamin intake. Large amounts of the sulfa drugs may block the action of the vitamins in the tissues. Certain vitamins are stored in the liver, and hepatic disease may prevent their storage on days when an excess is present, thereby failing to provide for periods of insufficient intake.

Question. What ocular expressions of vitamin-A deficiency have you found in human subjects in New York City?

DR. KRUSE. These occur in the conjunctiva near the limbus at the horizontal meridian and are chronic in type. There is thickening, opacification, and discoloration. These chronic changes are to be distinguished from keratomalacia and Bitot's spots, which are acute. The acute states in this region have all been superimposed on the chronic. The initial site is the last to clear when recession occurs.

Dr. Jolliffe. What is the relation between the conjunctival changes and those commonly seen in the skin?

Dr. Kruse. The skin changes do not appear in the absence of conjunctival changes which, however, may alone be present.

Question. Have you ever seen diabetic changes influenced by dietary or vitamin therapy?

DR. YUDKIN. Diabetes mellitus is a metabolic disorder that produces tissue changes in all organs of the body. The prominent changes observed in the ocular tissue are edema and vesiculation of the

pigment layers of the iris, curious focusing changes in accommodation, diabetic amblyopia, lenticular changes, and a retinopathy. The retinopathy is the complication most frequently encountered. I believe it occurs mostly in longstanding, uncontrolled mild cases, for it is far less common in diabetes of short duration or under good control from the start. The changes in accommodation are found at some stage in most diabetics. Usually, when an acute stage of diabetes is developing, some changes take place in the lens or the vitreous that produces a myopia, and it lasts from a few days to many weeks. A slitlamp examination during this curious focusing change has not revealed any disturbance of the tissue except occasionally the presence of edema and vesiculation of the pigment layer of the iris. This change in the iris does not disappear when the normal focus returns. The changes in the lens of badly controlled young diabetics are typical of the metabolic disorder. The diabetic amblyopia or retrobulbar neuritis of diabetes resembles that encountered in toxic amblyopia of tobacco and alcohol. The presence of these conditions in diabetes has accounted for the theory that some toxic element is distributed by the blood which is capable of damaging sometimes one or sometimes another area of the central nervous system.

True diabetes mellitus as we understand it today can be controlled by proper diet and insulin. If the diabetic shows manifestations of malnutrition, it is extremely important to supplement the well-balanced diet and insulin with some of the vitamins. Several reports have appeared, indicating that vitamin A has been beneficial to diabetics suffering from photophobia, and vitamin C has, in part, been responsible for a more rapid absorption of the various types of hemorrhages in the choroid and retina. A well-balanced diet

supplemented with a multivitamin combination and a regulated diabetic regimen will, in most instances, prevent or delay ocular manifestations associated with diabetes.

DR. KRUSE. In addition to the direct role of diabetes in nutrition, it should be remembered that in treating diabetes we in some ways produce a deficiency disease. The clinic patient used to be given diet lists with substitutions—such as, 3 Uneeda biscuits in place of certain vegetables, 4 Uneeda biscuits in place of potatoes—and when finances required these substitutions to be made, deficiency resulted. Now especially, are patients permitted to eat what they wish and the excess is covered by insulin.

Question. What is the present status of (a) blood examinations to determine vitamin deficiencies; (b) urinalyses to determine the same conditions?

DR. JOLLIFFE. At the present time, a 0.2-c.c. sample of blood can be used to determine vitamins A, C, total protein, hemoglobin, calcium, phosphorus, and one or two other factors. Urinalysis can indicate the amount of vitamin C, thiamin, and riboflavin escaping into the urine and indicate the degree of saturation of the tissues by these substances. These tests are useful in determining the recent dietary history of individual patients.

Dr. Solomon. Can these tests be used to determine the function and capacity of organs playing a role in the production and storage of these substances; as, for example, vitamin A to indicate liver function?

Dr. Jolliffe. This could be used as a liver-function test. It is likely that many doctors will use these determinations for estimating the function of various other organs.

Question. How reliable is dark adapta-

tion in determining vitamin-A deficiency?

DR. KRUSE. For technical and biological reasons it has a high degree of unreliability. Tests with three of the most widely used adaptometers showed that none of them gave a comparable curve, and that the threshold variations for different individuals were so large that a standard threshold could not be determined. There is no reason to believe that disadaptation is a sign of avitaminosis A, and there is some reason to believe that it is not.

Question. What evidence of nutritional deficiency have you observed in private practice?

DR. SOLOMON. It is undeniable that occasionally vitamin deficiency is seen in practice. We see cases of great undernourishment, with gastrocolic fistula or pyloric stenosis without evidence of specific avitaminosis. Although clear-cut vitamin deficiencies are seen, they respond well to the simple removal of the conditioning factors. Too many cases are considered so-called subclinical vitamin deficiencies. Loss of appetite, lowered work capacity, and various eye symptoms are loosely attributed to vitamin deficiency. While such patients improve with vitamin therapy, it should be remembered that every new treatment helps a neurotic. A patient with diabetic pseudotabes did not improve upon taking vitamins. Vitamins administered in a case of low-grade renal infection were without effect as regards the symptoms attributable to vitamin deficiency, but when the infection was cleared up every symptom was relieved.

DR. JOLLIFFE. Starvation does not cause vitamin deficiency. The only way to produce deficiency in animals is to starve them and then feed glucose. Asymmetrical deficiency is required for avitaminosis to present itself. When there is a con-

ditioning factor, it obviously calls for correction. The pathologic changes that have developed after years of mild deficiency are not going to be corrected by removing any factor. It will take months and years of therapy and, even then, some will be irreversible.

DR. KRUSE. Deficiencies that have been said to be widespread are not acute but are mild and so common as to have been considered normal changes. The dividing line between health and disease is not sharp and the evidence which is so great for animals has yet to be accumulated for human beings. There are several studies showing that the health of the pregnant woman and her offspring is improved by proper nutrition during pregnancy. Other studies of human beings have been made, but there must be more studies before the marked skepticism of the medical profession can be overcome.

The myopic child should not be denied a well-balanced diet supplemented by vitamins and minerals prescribed by the family doctor, but Dr. Yudkin has failed to check the advance of myopia with large amounts of vitamin D and calcium.

Question. Discuss Wernicke's central bilateral ophthalmoplegia.

DR. JOLIFFE. In this condition there is ophthalmoplegia associated with ataxia. Ophthalmoplegia, in general, may be due to many causes, but this particular syndrome will respond in a few days, and at times in hours, to fairly good doses of thiamin. The medical recovery will be very satisfactory, and there will be improvement in the ophthalmologic picture. The acute symptoms of polyneuritis, which may also be present, will disappear or be relieved. The ataxia is not changed.

Question. Discuss reversibility of ocular pathologic processes in vitamin deficiencies.

DR. KRUSE. Most stages of ocular pathologic change are reversible, although the reversal may be very slow. However, and especially in the end stages, there are actual lesions that will not be cleared up. For example, in long-standing avitaminosis A there may be destructive ulceration, corneal softening, even perforation with prolapse of the bulbar contents, and these changes are obviously not amenable to relief by diet. In general, reversibility is rapid in acute, slow in subacute, and very slow in chronic cases.

Question. In what way does organic disease bring about nutritional deficiency?

DR. SOLOMON. Examples may be cited from some abdominal cases now under treatment. A patient with gastrocolic fistula immediately eliminates, as a bowel movement, any food swallowed. A late case of periarteritis nodosa, because of circulatory impairment of the small intestine, has dysfunction with faulty absorption. Such faulty absorption also is present for similar reasons in a case of lymphoma and of tuberculous adenitis. Dr. Joliffe has given other examples in discussing conditioning factors.

Question. Has dystrophy of the cornea that occurs during the third decade or later any association with general nutritional disturbances or is it a purely local condition?

DR. YUDKIN. Dystrophies of the cornea occurring during the third decade or later are not directly associated with general nutritional disturbances nor are they a purely local condition.

The epithelial degenerations involving the epithelium and endothelium best represented by the epithelial dystrophy of Fuchs are not associated with a nutritional disturbance. The condition is probably an endothelial degeneration with subsequent epithelial involvement. Three cases of epithelial dystrophy of Fuchs

were treated with a well-balanced diet and large amounts of concentrate of vitamin-B complex for nearly four years. The vision has become worse and the bullae recur more frequently. Nodular and reticular dystrophies of the cornea are usually seen by the ophthalmologist when the condition is fairly well established in the ocular tissue. Some forms of the dystrophy have been recognized as early as during puberty.

The lesions are considered as familial and usually involve both eyes. The deposits of hyaline-like material in the superficial substantia propria may develop into a nodular type of Biber, Haab and Dimmer, or a ring-shaped type of Fleischer. There are many case reports on ocular dystrophy in the literature, and the authors almost unanimously agree that no effective treatment has been discovered, although various suggested measures have improved the condition of individual patients. The more important etiologic factors are evidence of impaired local nutrition and endocrine insufficiency, and the dystrophy may have a neurotrophic origin. With a better understanding of geriatrics, it may be possible that the aforementioned dystrophies may prove to be the result of some nutritional deficiency.

The nodular dystrophy of Salzmann has been reported as a noninflammatory and slowly progressive condition occurring in persons previously affected by phlyctenular keratitis. This condition calls to mind some experience with ocular disturbances that are still fresh in our memories. What has happened to all the cases of phlyctenular keratoconjunctivitis that were seen in the clinic annually previous to 1929? The doctrine of a well-balanced diet supplemented with cod-liver oil may be the reason why phlyctenular keratoconjunctivitis has almost entirely disappeared.

Are the fewer cases of interstitial keratitis of syphilitic and tuberculous origin which now appear annually in the clinics in this country due to fewer infections or to better resistance? In recent years there have appeared case reports wherein interstitial keratitis has been cured more rapidly by supplementing a well-regulated diet with cod-liver oil as an adjunct, some instances wherein large amounts of vitamin-B complex have accomplished the same miraculous repair to tissue, and more recently riboflavin has been given credit for rapid cure of interstitial keratitis.

CLINICAL PROGRAM

(Presented by the Department of
Ophthalmology, University
of Chicago)

MALIGNANT BILATERAL EXOPHTHALMOS

DR. BARBARA SPIRO said that R. S., a white man, aged 44 years, was first seen on January 22, 1945. In May, 1944, he had had a subtotal thyroidectomy elsewhere with an uneventful recovery. About 1½ months later he noticed puffiness and protruding of both eyes, which became progressively worse in spite of the ingestion of thyroid extract. Excision of conjunctival tissue had resulted in no improvement.

When seen in the Eye Clinic in consultation, the patient's vision was: O.D. perception of hand movements at 1 foot; O.S. 20/30. The Hertel exophthalmometer reading was O.D. 35-36 mm.; O.S. 29. The conjunctivas of the right eye

were extremely injected and chemotic, and the patient was unable to close his lids. The cornea was grossly wrinkled and granular, completely devoid of epithelium in the lower half. The fundus could not be visualized. The left eye was normal except for conjunctival injection; however, it could be closed only by force. External ocular movements were almost nil in the right eye and were restricted to 10 degrees in all directions in the left eye.

A diagnosis of malignant bilateral exophthalmos with impending perforation of the right eye was made. X-ray shields were applied for protection and 1-percent atropine ointment and castor oil were applied.

On January 25, 1945, a Naffziger decompression of the right orbit was performed in the neuro-surgical department, followed by a similar procedure on the left orbit 12 days later. Following operation, the decrease of exophthalmos and chemosis was slow, and the eyes could be well closed. The cornea of the right eye cleared very slowly. About one week following the second operation, high doses of thyroid were instituted, which helped to decrease the lid edema. X-ray therapy to the pituitary was given one month following operation. The exophthalmometer reading was O.D. 18; O.S. 16. The patient was discharged about six weeks after the second operation. One month later, the vision was: O.D. perception of hand movements at 3 feet; O.S. 20/16. The patient had taken no thyroid extract for the past month and the exophthalmos was exacerbated, the Hertel reading being O.D. 22, O.S. 21. He was advised to resume the taking of thyroid extract and to continue the local prescription as well as to wear tight-fitting goggles at night.

EARLY MALIGNANT EXOPHTHALMOS

DR. BARBARA SPIRO said that Mrs. D.

L., a woman aged 32 years, presented herself at the Eye Clinic on July 5, 1944. She had had a subtotal thyroidectomy for hyperthyroidism in December, 1943, and complained that the eyes were becoming more prominent since that time. She was taking 0.5 gr. of thyroid daily. Aided vision was 20/20 bilaterally; there was mild edema of all lids and limitation of extraocular movements upward. The Hertel exophthalmometer reading was O.D. 22, O.S. 23.

X-ray studies of the skull and optic foramina showed no pathologic change. The exophthalmos slowly became worse. In December, 1944, the patient received deep X-ray therapy to the pituitary gland in addition to thyroid extract by mouth. The exophthalmos decreased somewhat immediately after irradiation, but increased subsequently to its former status. She continued to receive thyroid therapy, and the exophthalmos has remained stationary for three months.

SIDEROSIS OF THE EYEBALL?

DR. WILLIAM ROSENBERG said that L. E. H., a white man, aged 47 years, was first seen in the Eye Clinic on April 16, 1945, complaining of poor vision in the left eye and stating that the iris of the left eye had become brown. Vision was: O.D. 20/16; O.S. perception of hand movements at 8 feet, with normal light projection, color identification, and ability to visualize his vasculature entoptically. About 2½ years ago he had been struck in the eye with a steel foreign body (he believes it to have been the right eye, but his wife remembers it as the left). Vision was reduced to a "faint glow" but within a week returned to normal. About two months later, he noted central blurring and haziness of the eye, and his wife noted that the iris, previously gray, was turning brown. A dull, inconstant throbbing pain developed in the left eye. All

signs and symptoms became progressively worse, and in the summer of 1944, an ophthalmologist was consulted. Under treatment the pain and photophobia gradually decreased, but vision continued to decline. General health has been good. An X-ray study of the chest six months ago was normal.

On examination, the iris of the left eye was chocolate brown in color and muddy. The cornea grossly showed brownish pigment around the limbus. The pupil was round and did not react to stimuli, although no synechiae were present. The anterior chamber was shallow. The slit-lamp revealed fine brown pigment dispersed throughout all corneal layers, in the anterior chamber, over the anterior lens, and iris. The lens was dense and yellowish, especially nuclear. The right eye was normal; visual fields were normal. X-ray studies of the chest and skull were normal; those of the anterior segment revealed no foreign body. Biopsy specimens of the cornea and aqueous were stained with potassium-ferrocyanide for iron as well as with hematoxylin and eosin. These revealed no iron, but many fine pigment granules. In consultation, the patient saw Dr. Von der Heydt, who thought this condition was from a complicated cataract, not from a foreign body. His report stated that there was an imbibition of the cornea by cell elements which may have been blood derivatives.

CONGENITAL CATARACTS AND HIGH MYOPIA

DR. WILLIAM ROSENBERG said that E. M., a white girl, aged 12 years, was first seen on September 28, 1943, complaining of cataracts since birth. Her aided visual acuity was 20/50 in each eye, and she was able to read 6-point type with either eye. The family history was significant, in that her father and three of four siblings (two males and one female) also

had cataracts, as did her paternal grandfather and a paternal aunt. A paternal uncle was normal and had four normal children.

Except for the lens opacities the eyes were normal. Refraction under cycloplegia did not improve visual acuity. Both lenses showed a generalized pitting of the anterior surfaces, imparting a "golf ball" appearance. The anterior cortices were studded with innumerable, lustrous, crystallike opacities, most densely packed centrally. The posterior cortices were similarly involved. The fetal-Y nuclei showed moderate degrees of opacification.

No further treatment was suggested.

The father of this patient, aged 54 years, was also presented. His complaints were similar to those of his daughter except that, in the past four years, his visual acuity had diminished to such a degree that he was unable to carry on an economic existence. His visual acuity with -16.75D. spheres was 3/200 in each eye; improvement could not be obtained by refraction. Both lenses showed packed floriform, hexagonal and irregularly shaped, singular opacities, most densely aggregated axially in the adult and embryonic nuclei and becoming more sparse toward the equators. The cortices were clear, and the nuclei had a spongelike multicysted appearance. Superimposed on this, there was moderate senile nuclear sclerosis. Visual fields were normal for large targets.

Extraction of the lens of the left eye was advised, with a guarded prognosis because of the high myopia and fluid vitreous. On December 28, 1943, a combined, extracapsular lens extraction was performed. Recovery was uneventful, but a moderately dense secondary membrane remained. A needling was performed on April 1, 1944, and again recovery was uneventful. One week later the patient re-

turned, complaining of pain, redness, and photophobia. He had a severe iridocyclitis and conjunctivitis, and stated that he had returned to work the day following surgery and that it was necessary to wipe his eyes frequently. Under intensive local and foreign-protein therapy, the iridocyclitis abated, and on May 3, 1944, the aided visual acuity was 20/40, and he could read newsprint.

Two weeks later he returned, complaining of a veillike shadow over the eye that had been operated on. Examination revealed a huge temporal and inferior retinal detachment, bullous below. Vision was 20/100. He was admitted to the hospital immediately, and four days later a microcoagulation operation was performed. Convalescence was stormy, vision was reduced to light perception, and the eye began to shrink. Five weeks after surgery, the eye was definitely phthisical.

The patient and his family insisted on the extraction of the lens of the right eye subsequently and, despite a very guarded prognosis, a combined intracapsular extraction was performed on November 1, 1944. He developed a mild iridocyclitis postoperatively which responded readily to local therapy and typhoid-bacilli injections. Recovery was thereafter uneventful. Aided visual acuity with a correction of $-1.25D.$ sph. $\ominus +1.25D.$ cyl. ax. 165° is now 20/25, and he can read newsprint easily. A prosthesis was fitted to the left phthisical bulb.

CATARACT, ECTOPIA LENTIS

DR. WILLIAM ROSENBERG said that R. R. L., a white man, aged 26 years, came to the Eye Clinic on May 8, 1945. His unaided vision was O.D. 20/200; O.S. 20/70; he could read 4-point type at three inches with the left eye and 24-point with the right. Glasses were of no aid. His present condition had existed since birth, and the vision with the right eye

had always been poorer than with the left. Diagnosis of ectopic lenses and pupils had been made by several ophthalmologists, and iridectomy of the left eye had been suggested.

The right eye was 5 to 10 degrees divergent in the primary position, and he fixated with the left eye. The pupils dilated only 2 to 3 mm. eccentrically with cycloplegics and mydriatics. In the right eye, the lens edge could be visualized only obliquely so that the entire pupillary space was still filled by the lens. In the left, there was a 1-mm. slit of aphakic pupillary space nasally; the zonule could be seen stretched across this space, through which, with a $+10D.$ sph. he could read 20/50 eccentrically. The fundus of the right eye could not be visualized; that of the left appeared normal.

It was felt that an optical iridectomy on the right eye would avail nothing, whereas it might help on the left, although there was a chance of inducing monocular diplopia. On the other hand, lens extraction with iridectomy might, if uncomplicated, offer a better visual result. The right eye was probably amblyopic. It was suggested that the right eye be operated on first to determine the response to surgery and, if successful, to contemplate a similar procedure on the left eye.

ECTOPIA LENTIS

DR. WILLIAM ROSENBERG said that G. H., a $4\frac{1}{2}$ -year-old white girl, was brought to the Eye Clinic on February 3, 1945, at which time visual acuity was 20/200 in the right eye; 20/100 in the left eye. Pregnancy and birth had been normal. The present condition was observed one month after birth. At two years of age, it was noted that the eyes "glimmered," and that she held objects very close to the left eye to see them. No other symptoms were observed except that she insisted on bright lights for play, even

during the day. Her general health and development had otherwise been normal.

Examination revealed bilaterally ectopic lenses. The pupils dilated well under cycloplegia, and the aphakic portions refracted approximately $+7.00D.$ sph. $\approx +1.50D.$ cyl. ax. 90° in each eye. The fundi appeared normal. Only very narrow aphakic slits were present in the undilated state.

Lens surgery was suggested.

RIGHT LATERAL-RECTUS PARALYSIS IMPROVED BY GIFFORD OPERATION

DR. MAURICE J. DRELL said that P. B., a boy aged 11 years, was first seen in December, 1944, with a history of a fall three months previously, with questionable momentary loss of consciousness, followed by redness and swelling of the right eyelids, after which diplopia and right convergence developed.

The left eye was normal. The right eye showed a 15-degree esotropia with inability to abduct the eye past the midline; dilation, irregularity, and poor reaction of the pupil; anesthesia of the cornea with fine, diffuse, superficial staining with fluorescein; and anesthesia of the upper lid and supraorbital area. Right vision was 20/100, although it was felt that this was at least partly due to inability to fixate properly because of the internal-rectus spasm.

The findings of right abducens palsy, pupillary disturbance, and partial, fifth-nerve involvement were considered traumatic in origin. A temporal shield and nail-polish occlusion of the right glass were prescribed. When no changes were noted after three more months, recession of the internal rectus, with attachment of the outer halves of the superior and inferior recti to the external rectus, according to the technique described by Gifford, was performed in April, 1945. At present, vision with the right eye is 20/25. There

is 15 to 20 degrees of right abduction, and fusion is present at 12 degrees of convergence. Temporary prisms have been ordered.

RUBEOSIS IRIDIS, BILATERAL

DR. MAURICE J. DRELL said that D. P., an office worker, aged 48 years, was found to have diabetes of a mild nature two years ago, during a medical examination which he underwent because of failing vision. When first seen in June, 1944, his corrected vision was O.D. 20/100; O.S. 8/200. Examination revealed severe, bilateral diabetic retinopathy. The iris of the left eye was atrophic and rubeotic; that of the right eye was normal at this time. On reexamination in April, 1945, the visual acuity was essentially unchanged but the rubeosis of the left eye was more advanced, and the iris of the right eye now showed very early rubeotic change. Tension was normal. With the aid of a high plus lens for the right eye and an additional hand telescopic attachment, the patient is just able to read newspaper at six inches. He has been taking lemon juice in an effort to halt the progression of the vascular changes. In view of the poor prognosis of the progressive retinopathy, he has begun the study of Braille.

OPHTHALMIC MIGRAINE

DR. MAURICE J. DRELL said that C. B., a woman, aged 24 years, consulted the Clinic in January, 1945, with a history of pain in the right eye and diminution of vision in both eyes since March, 1944. Associated with this there have been photophobia, considerable watering, and some redness of the right eye. Vision O.D. was 20/200; O.S. 20/40. There was a moderate ptosis of the right eyelid, and a mild ptosis of the left. No corneal sensation was felt in the right eye, and there was definite hypesthesia of the upper two

thirds of the right side of the face and tongue. The cornea showed scattered fine staining with fluorescein. Field studies, skull and optic-foramen X-ray studies, routine laboratory procedures, and neurologic consultation gave no findings of significance. An audiogram showed bilateral slight hearing loss.

In view of the right corneal anesthesia, glasses with temporal shields were ordered, and an effort was made to control the pain with salicylates. The use of X-ray therapy to the Gasserian ganglion has been considered, but in as much as this treatment has been found to aggravate the pain almost as frequently as it affords relief, such therapy has been deferred thus far.

HEMORRHAGIC GLAUCOMA AND RUBEOSIS IRIDIS

DR. MAURICE J. DRELL said that Mr. W. C., a man, aged 73 years, was first seen one month ago, with a history of blurring of vision with the left eye commencing in August, 1944. Several months later the vision with the right eye in the nasal part of the field also became blurred. There was no pain. Three months ago the vision with the right eye became much worse, and for two weeks preceding his first visit the right eye was extremely and constantly painful. Vision was: O.D. light perception only; O.S. 20/50, with the best correction. The right eye was markedly injected, very firm tactily, and the cornea was moderately edematous. Through the edematous cornea, a dilated, atrophic, rubeotic iris was seen. The fundus could not be seen. In the left eye the essential findings were: advanced sclerosis of the retinal vessels and degenerative macular disease. Tension was O.D. 61 mm. Hg (Schiotz); O.S. 16 mm. Hg. Intensive application of pilocarpine and eserine completely relieved the pain in the right eye and caused the corneal edema to

subside, although tension has never dropped below 35.5 mm. Hg (Schiotz).

Laboratory investigation, including fasting, blood-sugar, and glucose-tolerance tests, revealed nothing of significance other than a mild secondary anemia.

TOXIC AMBLYOPIA (TOBACCO AND ALCOHOL)

DR. MAURICE J. DRELL said that G. S., a toolmaker aged 33 years, was first seen in August, 1944, with a 3-months' history of progressively lowered vision which had reached the point where he was unable to continue work. His best vision at the time was O.D. 15/200; O.S. 20/100. He had been smoking two packages of cigarettes and drinking several bottles of beer as well as a moderate amount of whiskey daily. Field studies revealed a typical centrocecal scotoma in the right eye and a paramacular relative scotoma in the left eye. He was placed on massive doses of B complex, orally and parenterally, and showed no improvement for five months. After this time, he began to improve slowly so that by February vision was O.U. 20/20. In May, vision was: O.U. 20/16. Field studies still revealed small relative scotomas in the papillomacular area, but these were shrinking steadily. He has been back at work for several months. The diagnosis was toxic amblyopia caused by alcohol and tobacco.

BILATERAL IRITIS DUE TO SARCOIDOSIS

DR. C. KEITH BARNES said that Mrs. A. S., aged 58 years, has been under observation and therapy at the Billings Chest Clinic for pulmonary sarcoidosis for many years. She has also had a chronic, bilateral iritis and keratoconjunctivitis which has been studied in the Eye Clinic. Because the etiologic studies have been negative in all other respects, it is believed that the ocular pathologic lesions may be attributed to the sarcoidosis.

She exhibits rather striking brushlike cyclitic membranes of the pupillary spaces. The fundi are seen reasonably well and show no gross pathologic change.

EXOPHTHALMOS DUE TO RETROBULBAR METASTASIS OF PULMONARY CARCINOMA

DR. C. KEITH BARNES said that C. F., a white man, aged 40 years, came to the Clinic because the left eye had been swollen for four or five weeks. He was seen elsewhere in 1932, when bilateral cataract was diagnosed. His past history included the following items of significance. Twenty-five years ago, he had a five-story fall and suffered a skull fracture. There were no subsequent eye findings. The right arm was amputated at that time. He was told that he had a spontaneous pneumothorax two months ago. He had lost about 20 pounds in 18 months. He coughed frequently.

The major eye findings, in addition to bilateral nuclear cataracts, were as follows: The left eyeball was proptosed 9 mm. forward and 7 mm. downward, with adequate lid closure. Left extraocular movements were markedly reduced in all directions. A firm fixed mass could be palpated above the left globe. No bruit nor pulsation was present; the mass did not increase with jugular compression nor decrease with carotid compression. Through the peripheries of dilated pupils, the fundi appeared normal except for engorgement of the veins and constriction of the arteries of the retina of the left eye.

Pertinent general findings were: Wassermann test was negative. Skull X-ray studies were negative. On the chest film there was a uniform, markedly increased density involving the whole left side of the chest so that even rib shadows could barely be made out. The shift of the mediastinum to the left indicated that pul-

monary atelectasis, as well as pleural effusion, probably played a part in producing this picture. A biopsy specimen has not been taken of the orbital mass, but it is believed that mitotic figures would be demonstrated.

Robert Von der Heydt.

ROYAL SOCIETY OF MEDICINE

SECTION OF OPHTHALMOLOGY

June 8, 1945

UNUSUAL INTRAOCULAR FOREIGN BODIES

MAJOR C. DEE SHAPLAND presented two cases showing unusual intraocular foreign bodies.

Case 1. A sergeant was wounded on May 28, 1940, by a bullet splash from an enemy machine gun on the armored vehicle in which he was travelling. When hit, he saw a flash in front of his face and felt pain in his left eye. He was transferred to a Casualty Clearing Station, and while there was captured by the Germans. On July 23, 1940, he was discharged from hospital and received no further treatment during his long period of captivity. The patient stated that he had been "blind" in his left eye since the injury. He was repatriated on May 11, 1945, and was first seen by Major Shapland at Millbank on May 23, 1945.

The left eye showed a divergent squint of some 10 degrees, no active inflammatory signs, and there was an anterior iritic synechia to a perforating, corneal scar paracentrally at the 7-o'clock position. There were multiple, minute, glistening,

metallic fragments on the iris and in the iris stroma, especially below, where there was a ragged, narrow, complete iridectomy; the eye was aphakic with dense capsule, and there was no fundus reflex. The tension was normal, and vision was reduced to perception of light with good projection. The right eye showed no abnormality and had standard vision unaided.

On May 24, 1945, the left eye was put up to a giant magnet with a negative result, and immediately afterward the anterior synechia was divided with a Ziegler knife under local anesthesia and, at the same time, a capsulotomy was performed. The eye settled down uneventfully from the operation, and its vision is now 6/12 with aphakic correction (+12.50D. sph.)

The interest of this case was the fact that the injured eye, despite the presence of multiple nonmagnetic metallic fragments on and in the iris stroma for five years showed no active inflammatory signs nor evidence of degeneration resulting from chemical action. The nature of the intraocular metal must necessarily be a matter of speculation but was presumably derived from the German machine-gun bullet and was, therefore, probably a lead-nickel alloy.

Case 2. A captain, while examining a German underground cable by a roadside in Normandy, on June 17, 1944, pulled a piece of cord, and an explosion occurred. He was taken to No. 21 Field Dressing Station with multiple wounds of the face and hands and injuries to both eyes.

His face was much pitted and scarred from multiple fragments of stone of all sizes up to that of a large pea. The smaller fragments were quite superficial and were constantly being spontaneously extruded, the larger ones were deeper and were removed later from the mucous surface of both upper and lower lids, from

the plane of the orbicularis oculi in the left upper lid and just superficial to bone in the right frontal region.

The right eye showed considerable conjunctival and ciliary injection; small particles of stone in the sclera some 2 mm. from the limbus at the 9-o'clock position; slight superficial corneal scarring; no K.P.'s; mydriasis (atropine); fundus normal; tension normal; vision 6/24 unaided. On the left side there was very considerable blepharospasm and photophobia; the eye showed much conjunctival and ciliary injection; many minute particles of stone embedded in the sclera mainly adjacent to the limbus at the 3- and the 9-o'clock position; multiple perforating corneal scars; numerous minute foreign bodies on and in the iris stroma; pupil half dilated and fixed (atropine) with a firm posterior synechia at the 12-o'clock position; a traumatic cataract with central perforation in the lens capsule and lens matter extruding into the anterior chamber; a faint reflex with no fundus details; tension normal; vision perception of light with good projection.

The right eye was put on 1-percent atropine drops twice daily; the left eye on 1-percent atropine ointment, with hot bathings every four hours and penicillin drops (500 units /c.c.), two-hourly by day. On July 9, 1944, the radiologist reported that there were no opaque intra-orbital foreign bodies in either the right or the left eye, and on the same day, the left eye gave a negative response to the giant magnet. By July 18th, the eyes had become sufficiently quiet to allow removal of several particles of stone embedded in the sclera and episclera of both eyes.

The right eye was taken off atropine on October 1, 1944, but the left eye remained irritable for many weeks longer and at one stage developed fine K.P.'s with inflammatory cells in the anterior chamber. It became quiet eventually, how-

ever, and the patient was discharged from the hospital on November 5, 1944, with the right eye white, and vision 6/5 unaided. The left eye was quiet, with no K.P.'s and normal tension; the lens, however, was almost completely opaque; and vision was sufficient for counting fingers at six inches with good projection.

The interest of this case was the presence of multiple particles of stone intraocularly with the absence of pyogenic infection. In civil life, in my experience, an intraocular foreign body of stone is usually rapidly followed by the loss of the injured eye from panophthalmitis. Presumably the disruptive effect of the high explosive was sufficient so to disintegrate the road stones as to render them sterile. The patient received no systemic penicillin; but did have a course of sulfadiazine, a total of 20 gm. being given between June 22 and 27, 1944. The traumatic cataract in the left eye was needled. The eye is now aphakic, and central vision with correction is 6/12. The particles of stone in the iris stroma appeared unchanged, and the eye stood the needling quite well.

MYASTHENIA GRAVIS SHOWING RECURRENT MONOCULAR PARALYTIC MANIFESTATIONS

MR. SIMON BEHRMAN presented such a case in a woman. He said that, excepting for the paralytic phenomena, this patient remained throughout the period under review in excellent health and complained of no other myasthenic phenomena.

General medical, serologic, and neurologic examinations remained negative, apart from the oculomotor paralysis which, although subject to fluctuations, showed none of the diurnal variations characteristic of myasthenia gravis. Blood Wassermann reaction and the pupillary reactions have remained normal through-

out. The paralysis could be relieved rapidly and almost completely by diagnostic injection of prostigmine.

For treatment, oral administration of prostigmine was used. She made an almost complete recovery, and now shows only a slight paresis of the left superior rectus muscle.

EXOPHTHALMOS FOLLOWING ABRUPT DISCONTINUATION OF THYROID MEDICATION FOR OBESITY

MR. SIMON BEHRMAN presented the case of a woman, aged 48 years, who in 1935, after six months' treatment, "left off taking thyroid because a sister, who was also taking thyroid, became a wreck." This patient's eyes then became prominent, and she later received deep X-ray treatment on account of "thyroid trouble," with marked success. She now complains that she is putting on weight and that there is puffiness under the eyes. There is absence of lid retraction; the presence of exophthalmos is indicated by the exposure of the sclera below the lower border of the iris. Some puffiness is present around both eyes. She shows obesity, but otherwise her health remains good, and she is able to earn her livelihood as a driver of a delivery van.

Comment. Administration of thyroxine or thyroid extract does not lead to exophthalmos, except in a few cases. The rarity of this event in man can be gauged from the fact that Russell Brain (*Lancet*, 1936, v. 1, p. 182) was unable to find more than 20 instances in the literature. The present case resembles one of those included by him in his series. The case was originally reported by Stegman in 1906. After thyroid treatment, the patient developed palpitations and this led to the discontinuation of treatment. During the next few months, tachycardia, tremor, diarrhea, and loss of weight became conspicuous, and later exophthalmos ap-

peared. The condition of the patient improved greatly following deep X-ray treatment.

It would seem that administration of thyroid extract in a certain number of patients initiates a condition closely resembling, if not identical with, exophthalmic goiter.

EXOPHTHALMOS AND ENDOCRINE DISTURBANCE

DR. W. RUSSELL BRAIN opened the discussion on the subject. He said that the syndrome which he has called exophthalmic ophthalmoplegia is characterized by exophthalmos, external ophthalmoplegia, chemosis, swelling of the eyelids, and, in severe cases, papilledema. The puzzling feature in its etiology is that such a clinical picture may be associated with (1) thyrotoxicosis, (2) myxedema, or (3) a normal state of thyroid function. Two conflicting solutions of this problem have been proposed by British workers. Mulvany (1944) believes that there are really two forms of exophthalmos, which he calls thyrotoxic and thyrotropic exophthalmos. In his view, not only is their mode of production different, but the accompanying ophthalmoplegia is of different origin in the two forms. He attributes thyrotoxic exophthalmos to contraction of the orbital smooth muscles secondary to sympathicotonia, and the ophthalmoplegia to a myopathic condition of the ocular muscles, swelling of which causes the exophthalmos.

Rundle and Pochin (1944), on the other hand, maintain that exophthalmos in Graves's disease is due to an increase in bulk of the retroocular tissues. They claim to have shown that this increase is due to fat and is greatest in the eye muscles, in which the average fat content was doubled in a series of 17 thyrotoxic cases. Further, Rundle and Wilson (1944) state the bulging of the eyelids

associated with severe exophthalmos is not due to edema of the palpebral tissues, but to protrusion of the orbital fat increased in bulk. The same authors (1944) have carefully measured the ocular movements in cases of thyrotoxicosis and in patients with postthyroidectomy exophthalmos. In the former group, weakness of ocular movement is both less frequent and less severe than in the latter, but they believe it differs only in severity and not in kind. They note that in thyrotoxicosis, ophthalmoplegia may sometimes occur without exophthalmos, and they seem to attribute it to, or at any rate correlate it with, the increased fat content of the ocular muscles. They believe, then, that there is no difference in kind between the two forms, merely noting that there is an inverse relationship between thyrotoxicosis and ophthalmoplegia in Graves's disease. They propose to distinguish two forms of Graves's disease, an ophthalmic form without thyrotoxicosis, and a thyrotoxic form.

Clearly this view is unsatisfactory, for if the ophthalmoplegia is due to increased fat caused by the thyrotoxicosis, what can be the cause of it in the nonthyrotoxic cases? Either in both groups there is some common cause which is not thyrotoxicosis, or there are two causes—thyrotoxicosis in one group and something else in the other.

There is no considerable evidence in favor of thyrotoxic exophthalmos and ophthalmoplegia, however thyrotoxicosis may operate. In addition to the work I have quoted, there is some evidence that exophthalmos may be produced by the administration of thyroid extract and disappear on its withdrawal (Brain, 1936). There is also the improvement in both exophthalmos and ophthalmoplegia which sometimes follows thyroidectomy, or the administration of thiouracil. But neither exophthalmos nor ophthalmoplegia is

usually severe in thyrotoxicosis, except, perhaps in older patients.

What is the evidence for thyrotropic exophthalmos and ophthalmoplegia? There is a considerable volume of experimental work which shows that exophthalmos can be produced in guinea pigs by the thyrotropic hormone of the pituitary. Recent work has shown that this is due to edema of the orbital tissues (Smelser, 1943; Pochin, 1944); and Aird (1940) has reported histologic changes in the ocular muscles of the experimental animal similar to those found in exophthalmic ophthalmoplegia in man. This, of course, does not prove that exophthalmic ophthalmoplegia occurring in the absence of thyrotoxicosis is due to a thyrotropic hormone of the pituitary, but it does seem to be established that that hormone can produce a similar picture in animals and does so by means of orbital changes distinct from those obtaining in thyrotoxicosis. There is thus, in animals at least, and probably in man, evidence favoring both thyrotoxic and thyrotropic exophthalmic ophthalmoplegia. The failure to distinguish different causes for what appears to be the same ocular disturbance would explain some apparently conflicting results of treatment. Thiouracil or thyroidectomy would benefit the patient with the thyrotoxic form, though both can help to cause the syndrome in another way. Thyroid extract could hardly improve the patient already thyrotoxic but might well help one whose exophthalmos was associated with myxedema or rapid gain in weight; while either ovarian or testicular or thyroid extract might improve the exophthalmos due to the thyrotropic hormone, by inhibiting the production of this hormone by the pituitary.

Dr. Brain also said that since he had published an earlier paper (1937), he had seen 30 more cases, making 61 in all. The sexes are equally affected, and the av-

erage age is 50. Out of 61 cases, the condition followed thyroidectomy in only 11 and thiouracil in 1. In the postthyroidectomy group, males are affected at least four times as often as females. Since females get hyperthyroidism 9 times as often as males, males are 36 times more likely than females to get exophthalmic ophthalmoplegia after thyroidectomy for thyrotoxicosis. This striking sex difference seems to favor an endocrine factor in etiology rather than mere increase in weight or myxedema.

For treatment, Dr. Brain said that he had chiefly used estrin for both sexes. The results are mostly disappointing, occasionally very good. Most patients improve up to a point. He had increased the dose up to 20 mg. of stilbestrol daily in some cases.

EXOPHTHALMIC OPHTHALMOPLÉGIA AND ITS RELATION TO THYROTOXICOSIS

PROF. IDA MANN gave a paper on this subject which has been published in the *Journal* (June, 1946).

Discussion. Dr. S. Leonard Simpson said that he would like for a moment to depart from a close view of the end-results of illness, and urge how very much might be done by a prophylactic psychiatric approach to the problem. Anxiety and shock play an etiologic part both in thyrotoxicosis and in exophthalmic ophthalmoplegia. This is also true of duodenal ulcer, effort syndrome (D. A. H.) and some forms of hypertension, from which it appears that the nature of the derangement depends very much upon which organs or tissues of an individual are susceptible to the stimuli which come from the hypothalamus and perhaps from the pituitary. Are we not looking at the end-results of a psychogenic-hypothalamic syndrome?

Experimental evidence indicated that the thyrotropic hormone alone produced

exophthalmos, and although thyroxine might augment this effect, he did not believe that thyroxine alone could produce exophthalmos in man as distinct from lid retraction. Theoretically, withdrawal of thyroxine could, as a release phenomenon, produce the secretion of thyrotropic hormone, but he had seen many hundreds of cases of people who had had very large doses of thyroxine, producing sweating and tachycardia, and he had never himself seen—although a few cases had been reported—exophthalmos of any severity produced by thyroxine alone.

Concerning the group which Dr. Brain had separated, one must remember that the ophthalmoplegia was not necessarily present in the early part of the syndrome, so that there was a gradual transition from exophthalmos to exophthalmic ophthalmoplegia. The group looked different, the age was different, and the sex incidence (predominantly male) was different.

He would suggest the following theory: If it was accepted that the pituitary thyrotropic hormone produced exophthalmos, both in Graves's disease and in the exophthalmic ophthalmoplegic group, in the latter the thyroid was incapable of responding to the thyrotropic hormone. This was not improbable on clinical grounds. First of all, there was the age of the patients to be taken into consideration—about 50 years—and although one could get Graves's disease in old people, it was much rarer; then, again, the bulk of the cases was in men, in whom the thyroid was much less labile than in women. The theory could be put to the test by injecting these people with thyrotropic hormone, and seeing if a raising of the basal-metabolism rate was induced. The theory certainly appeared to apply to that type of exophthalmic ophthalmoplegia which followed extensive thyroidectomy, and which was as-

sociated with a low metabolic rate.

It was recognized clinically that toxic adenoma as distinct from Graves's disease was associated with minimal eye change, and rarely recurred after thyroidectomy. The reason for that would be that in the toxic adenomas it was not the thyrotropic hormone that was operating, but the primary activity of the thyroid gland. This was quite comparable with other endocrine diseases. Thus one might have either a single nonrecurrent cystic ovary, or multiple cystic ovaries which regenerated after one ovary had been removed and part of the other. The same held good for the adrenal glands.

He thought that testosterone was more logical for use in men than estradiol, which was more logical in women. Testosterone was as likely to inhibit the pituitary as was estradiol, and massive estradiol therapy was associated with retention of fluid. Neither hormones nor deep pituitary radiation could produce satisfactory results where irreversible secondary changes had taken place in the orbit.

Mr. E. E. Pochin referred to some of the quantitative data that he had obtained with Mr. Rundle. They had examined a series of 17 cases of thyrotoxicosis coming to necropsy, including 6 diagnosed as having exophthalmos, and had made a complete removal and analysis of the orbital contents. Where present, the exophthalmos had been of the simple type common in Graves's disease and not the so-called "malignant" or severe form.

It was found that the bulk of the orbital tissues was increased by an amount corresponding to the displacement of the eye observed in these cases. The increase was due to an excess of fat in the orbital structures, affecting particularly the skeletal eye muscles in which this ether-extract component was more than doubled. It was of significance that this change in the eye muscles was found in

15 of the 17 cases and not merely in those with exophthalmos.

In the light of these findings, what was the probable relationship between simple and "malignant" exophthalmos? It has now been shown that in simple exophthalmos, orbital tissues and particularly muscles were increased in bulk. In addition the careful work of Rundle and Wilson on ophthalmoplegia in thyrotoxic subjects, which his own measurements fully supported, showed limitation of ocular movement also to be frequent in simple exophthalmos. It thus appeared that each of these phenomena occurred in mild degree in mild or simple exophthalmos, and more severely in severe or "malignant" exophthalmos. Was "malignant" exophthalmos merely a more advanced, and secondarily complicated stage of simple exophthalmos?

He would suggest one hypothesis which was very far from being proved but which might provoke investigation. It was possible that, as orbital-tissue bulk increased in simple exophthalmos, a stage of severity was reached at which the vascular drainage of the orbit was mechanically impeded. The added orbital

bulk then started the rapid progression of malignant exophthalmos. with its severe protrusion, clinical evidence of congestions, and post-mortem findings of edema and later fibrosis. On this view it seemed likely that any rapid gain in body weight, such as might follow thyroidectomy, could in an exophthalmic subject increase the bulk of the orbital tissues enough to tip the scale and precipitate the progressive changes of "malignant" exophthalmos.

Prof. Ida Mann said that orbital decompression had not been done in any of her series (see the June, 1946, issue of this Journal). She knew that Mulvany had stated that if one had to deal with the malignant type one must perform Naffziger's operation to save the eye, but she thought she had shown that tarsorrhaphy plus the administration of thyroid extract did save the eye without this. Orbital decompression was, of course, a grave operation whereas tarsorrhaphy was not; in any case, with proper endocrine treatment the condition should subside, and the large mutilating operation of removing the orbital roof should not be necessary.

THE DEPARTMENT OF SOCIETY PROCEEDINGS WOULD LIKE TO OBTAIN THE SERVICES OF ONE WHO CAN TRANSLATE (AND ABSTRACT) SPANISH CONTRIBUTIONS. PLEASE WRITE

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to *Miss Emma S. Buss*, 121 Woodbine Avenue, Wilmette, Illinois. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, *Miss Emma S. Buss*, 121 Woodbine Avenue, Wilmette, Illinois. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE 1946 SPRING OPHTHALMIC MEETINGS

Many noteworthy events occurred during the delightful concentrated dose of ophthalmic and general meetings held in San Francisco from June 26th to July 5th, to make this a most enjoyable and fruitful occasion. The very lovely and unique city of San Francisco put on its most heavenly weather, for the sky was unreasonably blue, the sun was always there, and fog was conspicuous by its absence. There was an aura of relaxation, peace, and good fellowship, accentuated

by a short trolley strike, surrounding the visitor and native alike. Our San Francisco colleagues combined remarkable efficiency with hard work in their local committees with pleasurable and gracious hospitality. Many ex-medical officers attended their first post-war meetings and were obviously hungry for the varied ophthalmic fare spread before them. It was good to have them back with us once more. The chief leaven or ferment was the presence of Sir Stewart and Lady Duke-Elder of London. Sir Stewart, fresh from Northwestern University

where he had just received the honorary degree of Doctor of Science, radiated bouncing energy and friendly good nature. Gracious Lady Duke-Elder quickly won the affection of all of us and of our own ladies, too. They were guests of honor of the American Ophthalmological Society, which presented Sir Stewart, on June 27th, with the Howe medal for distinguished service to ophthalmology and elected him to honorary membership. The American Medical Association likewise made him an honorary member, and the Association for Research in Ophthalmology went one step better and elected both of them to honorary memberships, for Lady Duke-Elder is an ophthalmologist of distinction in her own right. All of these honors were graciously and modestly received and unanimously applauded. It is unnecessary to add that Sir Stewart and his Lady were the hit of the whole show, and all of us had many opportunities to meet and get to know these delightful people whom we now feel to be truly one of us.

The American Ophthalmological Society opened the events on June 25th. The scientific program was, on the whole, excellent and thought provoking. It is always difficult to single out the outstanding papers of this Society. The program offered much variety so that individual interests were well satisfied. The paper by Atkinson and Von Sollmann on "Mercury in the lens;" by Haden on the "Development of ectodermal framework of the optic nerve;" by McLean and Brambel on "Dicumarol and rutin in retinal vascular disorders," and by Berke on "Tenotomy of the superior oblique muscle within its sheath," seemed to this reporter to be particularly meritorious. Sir Stewart gave as his address a brilliant philosophical discussion of "Ophthalmology during the war, and in the future" that closed with the thought-provoking remark that it is up to the United States to keep the

torch of ophthalmology alight until Great Britain and the European continent have a breathing spell in which to recover, an event that may require several decades. The idea behind Parker Heath's paper on "Ophthalmic assistance at professional level," promoting the idea of ophthalmic technicians, trained at the university level and by medical teachers, was unanimously approved by the Society. This somewhat revolutionary and certainly evolutionary concept, if carried out, will prove to be a great boon to the ophthalmologist charged with the responsibility of professional eye care to the people, to industry, and to the Armed Forces.

John W. Burke of Washington, D.C., was elected president, Henry C. Haden of Houston, vice president, and Walter S. Atkinson of Watertown, N.Y., secretary and treasurer. Eighty-five members and 99 guests registered. The next meeting will be in Hot Springs, June 4, 5, 6, 1947.

On Tuesday, July 2d, the Association for Research in Ophthalmology held its 15th Scientific Meeting. As is customary, eight papers of research nature were presented. The program was excellent and well received. The field of ophthalmic research is rapidly growing, and the Association is gradually coming into its own, although its growth is hampered to some extent by the fact that so few nonmedical research workers in ophthalmology have joined, although they are entitled to belong and are assured of a hearty welcome by all members. Efforts should be made to enroll these individuals who are so necessary to ophthalmology and encourage them to take an active part in the guidance of this Association.

The Section on Ophthalmology of the American Medical Association held its scientific sessions in the mornings of July 3d and 4th, and combined with the Section on Nervous and Mental Diseases on July 5th as a joint session; 225 members

were registered. Under the very able direction of its chairman, Frederick C. Cordes of San Francisco, the Section program contained many papers of note and value. The chairman's address on "Ophthalmology's postwar responsibilities and opportunities" discussed the urgent problem of postgraduate training in ophthalmology and contained many constructive ideas. The guest of honor of the Section was Vice-Admiral Ross T. McIntire (MC) U.S.N., whose blue and brass uniform gave a scintillating color to the platform for the short time that he remained with the Section. The title of his paper "The role of ophthalmology in the Navy during wartimes" does not cover the full scope of his address, for the future of ophthalmology in the Navy was, in the opinion of this editor, the most important part of his talk. Admiral McIntire blamed what shortcomings ophthalmology in the Navy incurred upon poorly trained ophthalmic surgeons. He did not touch, of course, on the failure of the Navy personnel office to place the well-trained ophthalmologists in strategic positions where they could do the most good. Nor did he mention the fact that there was no consulting ophthalmologist in the Bureau of Medicine or Surgery of the Navy, who might have been of great assistance in the very great difficulty of proper assignment. But the future of ophthalmology in the Navy, if Admiral McIntire's schemes are fulfilled, should be particularly bright and encouraging to our great and important specialty without which neither the Army nor Navy Medical Corps can carry out their obligations for the proper professional care of the sick and wounded.

The scientific program was unusually good, especially when one considers the difficulties of assembling a program under these postwar conditions. There were several new ideas presented. Swan's paper on "Esotropia following occlusion"

focused attention on a condition that can be both annoying and embarrassing; Chandler's paper on a "Neglected cause of secondary glaucoma in eyes in which the lens is absent or dislocated" brought out a new thought; namely, that aphakic glaucoma may be due to a block between the posterior and anterior chambers. He showed pretty conclusively that iridectomy or iris transfixion cures this trouble. Barkan's paper on "Congenital glaucoma" gave impressive evidence that the operation of goniotomy which he devised, is of great value and is probably here to stay. Kuhn's paper on "Industrial ophthalmology" outlined the overwhelming field of work in this specialty and focused our attention on the problem of answering the increasing clamor of Industry for ophthalmic help. The other papers likewise deserve to be singled out for mention, but space does not permit. The able secretary of the Section did a commendable job in presenting to us such a splendid menu of ophthalmic fare.

The moving-picture program contained several items of ophthalmic interest and was well attended.

The Section was represented in the scientific exhibits by five noteworthy exhibits. Lack of space prevented more being shown. The splendid exhibit of A. D. Ruedemann of Cleveland, Ohio, on "A permanent plastic eye" was awarded one of the few gold medals (Class I) by the American Medical Association for originality and excellence of presentation. This award, so richly deserved, is a matter of great satisfaction to the Section.

The Section without a dissenting voice or vote adopted a resolution declaring it ethical for a doctor of medicine to lecture to or instruct nonmedical groups or individuals on matters that are pertinent to the prevention of blindness or important to the visual health and welfare of the people.

It was a matter of great regret to all

members of the Section that its vice-chairman, Grady Clay of Atlanta, was unable to be present because of illness. A message of affection, esteem, and sorrow was officially sent to Dr. Clay by the Section.

The officers elected for the 1947 Session were Derrick Vail, Chicago, chairman; Warren D. Horner, San Francisco, vice-chairman, and Trygve Gundersen, Boston, assistant secretary. Dr. Robert Masters, Indianapolis, continues as secretary. The next meeting will be held in Atlantic City, N.J., on June 8th and will celebrate the 100th anniversary of the founding of the American Medical Association. It promises to be a gala event and a magnificent performance.

Derrick Vail.

THEORIES CONCERNING MYOPIA

In the garden of ophthalmic science the problem of the causation of myopia is a hardy perennial. Whether presented before specialists or general physicians, the subject usually draws an audience. It is also a fertile field for editorial comment!

For many years the belief that close work or study was largely responsible for the production of myopia held almost undisputed sway. The more recent tendency, however, has been to regard refractive errors as dependent chiefly upon heredity. This point of view has greatly modified our attitude toward the myopic school child. The late Harrison Butler, prominent English writer on refraction, felt that the near-work theory had caused considerable injustice to myopes, whose ocular defect had often prevented their holding scholarships or becoming teachers. Sorsby considers nearsightedness as a problem in biology, and interprets low and medium myopia as a "nonpathologic and nonpathogenic variation."

In a recent paper, Lindner (Klinische

Medizin, Vienna, 1946, part 1) writes as a very stalwart adherent of the view that close work plays a most significant part in development of myopia. He rigorously decries the tendency of recent handbooks, especially those dealing with heredity, to explain lengthening of the eyeball in myopia as due, not to stretching, but to the hereditary influence of growth.

Unfortunately for all the disputants, and especially for those who are disposed to be dogmatic as to the influence of near work upon the development of myopia, the bases for discussion are so relatively obscure, and hereditary and environmental influences so complicated, that final and infallible scientific conclusions are well-nigh impossible. In spite of a certain German ruler now probably defunct, all civilized peoples of the world have undergone so much hybridization as greatly to complicate the study of their heredity. The more confused the mongrel's descent the more difficult its analysis.

An attempt to study the problem in a primitive people that has undergone very little mixture with other races was made some years ago by Stig Holm (see editorial, *American Journal of Ophthalmology*, 1938, volume 21, page 680). Holm's material was found among the inhabitants of Gaboon, French Equatorial Africa, who belong to one of the most ancient strains of the Negro race. These natives showed tendencies in ocular refraction, from childhood to old age, more or less parallel with those found among the civilized nations of the world. On the whole, the refractive variations were less conspicuous than among civilized communities.

Generally speaking, hybridization makes for variability in the descendants. According to the anthropologists Keith and Bolk, primitive peoples display a quality called "infantilism," as opposed to the quality of "progressivity" which accompanies the mixing of breeds. High myopia and other

extreme refractive errors are explained by certain authors including Holm as representing morbid or exaggerated manifestations of the "progressive" quality of variability.

Lindner has developed his own anatomic explanation for the scleral stretching found in association with marked degrees of myopia. Obviously, this stretching does not depend upon increased tension of the eyeball. But it has frequently been blamed upon yielding of the sclera to normal ocular pressure, a yielding which becomes greater as we approach the macular region. How, asks Lindner, does this thinning process develop?

Heine is quoted as having shown, by anatomic study in high unilateral myopia, that the much larger, highly myopic, eye contained a smaller mass of scleral tissue than the normal eye. Lindner points to the frequency with which, in the areas of greater scleral stretching, there may be seen so-called "varnish cracks," corresponding to breaks in the lamina vitrea, analogous to the gaps associated with stretching of Descemet's membrane.

Connective tissue, says Lindner further, is softened by inflammation, being digested by ferments arising partly from the blood serum and partly from the white blood cells. This process, he argues, may develop from simple congestion without inflammation, by reason of the toxic effect of carbonic-acid gas, aided by a certain amount of blood serum exuded from the capillaries. The process would be further emphasized by any damage to the capillaries.

Lindner is disposed to believe that in high myopia not attributable to excessive retinal labor, there is a deficiency in amount of nutrient protection of the macular region, and of the retina generally, normally furnished by the densely packed capillary network of the choriocapillaris. He admits that even in very high myopia the retina of the macular

region shows very little stretching, but explains greater stretching in the periphery on the ground of a lesser capacity for resistance there!

Lindner's complicated theory calls for one qualifying explanation after another. He explains the lower incidence of myopia in the United States on the ground that school study is less exacting among American children. But, he says, we in the United States have a greater incidence of late myopia, on account of greater intensity of study in college. He quotes from Nowak the record of a family in which both parents, immigrated from Europe, were high myopes but their nine children showed no myopia; yet, ignoring the caprices of heredity, he is disposed to explain this record on the basis of modified conditions of living and study in the United States!

One wonders what happens to the nutrient control of the choriocapillaris in those numerous cases of high myopia in vigorous and well-built American high-school children addicted to swimming and other sports, and living in country towns under excellent climatic and nutritional conditions.

In considering the problem of myopia, it may be well to assume that not the single element of heredity, not nutrition alone, not the influence merely of study or other close work, but all three factors jointly and in varying degree, may be responsible for the anomalous optical measurements of myopic eyes. The greatest practical benefits are likely to be derived from consideration of every detail presented by the individual patient.

W. H. Crisp.

WILMER RESIDENTS ASSOCIATION MEETING

The fifth clinical meeting of the Residents Association of the Wilmer Institute was held in Baltimore, in the Wilmer

Institute of the Johns Hopkins Hospital, on April 25th to 27th.

This Residents Association is composed solely of the men who have held the position of Resident Ophthalmologist in the Johns Hopkins Hospital. The Wilmer Institute was founded in 1925 when the first Resident Ophthalmologist was appointed. There are now 21 men who have held this position. It represents the final appointment of five resident years' service on the Institute staff, beginning as a House Officer, and progressing through junior and senior Assistant Residences until the Resident is finally selected for appointment from his group. The Residents Association therefore represents a cross section of activities of the Wilmer Institute from its founding to the present time.

The Association was organized as such in 1937, when the first formal meeting was held. The original purpose of the meeting was to provide an opportunity for reunion of Residents and other alumni of the Institute and to present to them a review of the various activities of the Institute during the preceding year. To this end the meetings are partly social and partly scientific. At the first meeting, a few ophthalmologists from neighboring cities were invited as guests of the Residents Association. The number of such guests increased each year, until the meetings were suspended during the war. The recent fifth meeting is the first one held since 1941. Twenty of the 21 members of the Residents Association were present, together with a number of other alumni, old Assistant Residents and Internes, and approximately one hundred out-of-town guest ophthalmologists.

The scientific program was held Thursday and Friday, mornings and afternoons, and on Saturday morning. Luncheons were served in the library of the Wilmer Institute. A general buffet supper was held Thursday night, and various in-

formal dinners were held Friday evening. After the adjournment of the meeting, the Residents' dinner was held Saturday night.

The scientific program consisted of papers presented by the staff of Wilmer Institute and by former Residents. The Thursday morning program consisted of a paper on the present status and value of retrobulbar alcohol injections by Dr. Maumenee; a study of contusion injuries of the eye by Dr. B. L. Rones, based chiefly on material in the Army Medical Museum collected during the recent war; a paper on the ocular signs of subdural hematoma by Dr. Frank Walsh; a report by Dr. Samuel McPherson on the results of cyclodialysis operations which is in print by the American Journal of Ophthalmology. The morning program was closed by a moving-picture demonstration by Dr. J. S. Guyton on various ptosis operations. Thursday afternoon's program was a presentation by Dr. Woods of the paper by Dr. Chesney and him on an immunologic theory for the pathogenesis of interstitial keratitis, based on their experimental work of the last six years and recently published in the Journal of Experimental Medicine and the American Journal of Ophthalmology. This was followed by a symposium of three papers on irradiation therapy with the beta rays of radium and experimental work on the effect of these rays on the ocular tissues. A portion of this work will be presented at the forthcoming Academy Meeting. The session was closed with a clinical-pathologic conference presented by Drs. Hoffman and J. S. Friedenwald. The Friday program consisted of papers on muscle surgery by Drs. Angus L. McLean and John M. McLean; a very interesting paper by Dr. Townley Paton on the corneal-transplant operation and the Eye Bank in New York; a second paper by Dr. Woods on focal infection; and closed with Dr. Friedenwald's presentation of

the Gifford Memorial Lecture of the interpretation of retinal vascular lesions, recently delivered in Chicago and as yet unpublished. The afternoon program consisted of papers by Dr. Snell on scleral disease associated with rheumatoid arthritis in which he showed present in the same eye the different pathologic pictures commonly associated with scleromalacia perforans and mesial scleral dehiscence; by Dr. Maumenee, detailing his further investigations on the relationship of the virus of epidemic keratoconjunctivitis to the virus of herpes simplex; by Dr. E. L. Burky on Brucellosis; and a paper by Dr. J. S. Haas on recent developments on prostheses for ophthalmology. Then as sequel to this paper, Dr. Cutler reported the developments in this field on his service at the Dibble General Hospital, and gave a moving-picture exhibit of his recently developed technique and startling brilliant results. The session closed with a paper by Dr. Guyton on decompression of the orbit, which is in press for the forthcoming number of "Surgery," which is to be the memorial number for the late Dr. Walter Dandy, whose recent tragic death is mourned by all ophthalmologists and surgeons alike. The concluding session on Saturday morning consisted of an interesting report by Dr. Randolph, former consultant in ophthalmology in the Surgeon General's office, on the organization of ophthalmology during the past war. This was followed by a paper by Drs. Owens and Hughes on the complications of cataract extraction, which was presented at the recent meeting of the A.M.A., and by a report by Dr. Fred M. Reese on corneal changes caused by atabrine. Dr. Wm. F. Hughes then gave a report of his investigations on chemical burns of the eyes, a portion of the research on vesicant injuries by war gases in the Wilmer Institute sponsored by the Office of Scientific Research and Development

under the direction of Dr. Friedenwald. Dr. Burky gave a paper on sensitivity to lens protein and to staphylococcus toxin, on the synergistic antigenetic action of toxin in stepping up the weak antigenic action of lens protein. The program was closed with papers by Dr. Samuel A. Talbot and Dr. Fred Crescitelli on experimental work on ocular neurophysiology and a spectacular exhibit of the method of plotting a cortical map of the retina by retinal stimulation and picking up the cortical response with a cathode-ray oscillograph.

It is hoped that these meetings will hereafter continue as an annual affair, although the limits of space and the number of guests may in the future necessitate moving the actual meeting from the Wilmer Institute to a larger lecture hall in the Johns Hopkins Hospital.

OBITUARIES

JAMES WATSON WHITE

1876-1946

Dr. James Watson White died May 15, 1946, after a brief illness at the Mountinside Hospital, Montclair, New Jersey, in his 70th year.

He was born in New Hamburg, New York, July 3, 1876, the son of Richard Watson and Sarah Celina Myers White.

After graduating from Mount Beacon Military Academy, Beacon, New York, he taught school in his native Dutchess County for five years. In 1905 he received his M.D. degree from Albany Medical College and was in general practice from 1905 to 1913.

Dr. White became associated with Dr. Alexander Duane in 1914 and remained with him until the latter's death in 1926. The knowledge and understanding of the extraocular-muscle anomalies that this association offered were soon expressed

in Dr. White's authoritative discourses on the subject. It was with keen interest and an investigative mind that he continued with this important work and became an international authority on the subject. While Dr. White contributed many important and original observations in his lectures and writings (among

which is the "Recession of the inferior oblique"), teaching was his greatest love.

For the past 25 years he had spent much of his time in collecting and devising teaching material and in organizing and actively teaching courses on the subject of ocular-muscle anomalies in various medical societies, hospitals, and at his office. He gave freely of his time and knowledge, carrying on an extensive correspondence with his students and colleagues, as a follow-up on their work with him. He presented this difficult subject in such a vital and understandable manner, that the demand for his work was difficult to fill. It was almost solely

through his efforts that the important contributions of both Dr. Duane and Dr. White on ocular-motor anomalies became of practical use to many ophthalmologists.

He was a sincere and truly great clinician and teacher, sparing no effort to help the individual student. His now familiar "Dr. White's Diagnostic Card" was originally designed to clarify the diagnostic position of the eyes to a single member of a relatively large class. To students he was practical, patient, and considerate and showed an appreciation of their need and an ability and willingness to help. He had the insight and broad, comprehensive viewpoint of a great humanitarian.

Dr. White had been on the staff of the New York Post Graduate Medical School and Hospital since 1919, was Associate Professor of Clinical Ophthalmology at the Medical School from 1934-1938, and Professor of Clinical Ophthalmology, Executive Officer of the Medical School's Department of Ophthalmology, and Director of the hospital's service of Ophthalmology from 1939 until his death. The school is affiliated with Columbia University. Many specialists took advanced courses under him.

He was consultant at Roosevelt Hospital, New York, Brooklyn Eye and Ear Hospital, Brooklyn, New York, Mountainside Hospital, Montclair, New Jersey, Essex County Contagious Disease Hospital, Belleville, New Jersey, and the Newark Eye and Ear Hospital, Newark, New Jersey. He was attending surgeon at the Herman Knapp Memorial Hospital from 1914-1933 and former consultant at the Vanderbilt Clinic and Sloan Hospital in New York.

Dr. White was active in numerous medical societies, was always vitally interested in scientific programs, and thoroughly enjoyed the association of his colleagues. He was a member of the Ameri-

can Medical Association, New York State and County Medical Society, New York Academy of Medicine, American Ophthalmological Society, American Academy of Ophthalmology and Otolaryngology, New York Ophthalmological Society, and Orange Clinical Society, Orange, New Jersey. He was chairman of the Ophthalmological Section, Medical Society of the State of New York in 1925; chairman of the Ophthalmological Section of the New York Academy of Medicine in 1938 and 1939.

As a person, Dr. White was considerate, generous, friendly, and possessed a fascinating wit and sense of humor. He had a unique and natural approach to people that was immediately disarming and was loved by all who knew him. In the clinics or at his office, the observer never ceased to wonder at the ease with which he immediately gained the affection and coöperation of children.

His interests and hobbies were many and varied. Perhaps the most important to him was fishing, usually in the vicinity of his summer home in the Thousand Islands, on the St. Lawrence River, that he loved so much.

Not only ophthalmologists, but all who had the privilege of his friendship have suffered a great loss in the death of Dr. James Watson White.

He is survived by his widow, Mrs. Margaret McClellan White, a daughter, Miss Betty White, and a sister, Miss Mary D. White.

CASSIUS D. WESCOTT
1861-1946

Dr. Cassius D. Wescott was born in Salisbury Center, New York, May 25, 1861, and died in Chicago on May 6, 1946. He received his early education in the Chicago public schools and graduated from Rush Medical College in 1883. Becoming interested in ophthalmology a few years after graduation, he gave up general practice in 1894 to come under the preceptorship of E. L. Holmes until the latter's death.

Dr. Wescott organized the first course in practical refraction at Rush Medical College. While he had a large surgical practice, in his latter years he became interested in the study of the fundus in its relation to the general health, especially of his older patients. His interest in the study of ametropia and the phorias consumed the greater part of his time during the last 10 years of his life.

As a teacher, both of his students and the younger men who came to him as assistants, he was dynamic and, at times, dramatic. If he demanded much of those who were associated with him in the hospitals, clinic, or office it was always evident that he drove himself at a greater pace.

He was honored by being chosen president of the Chicago Ophthalmological Society, chairman of the Section of Ophthalmology of the American Medical Association, president of the American Ophthalmological Society, and president of the Institute of Medicine of Chicago.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |

GENERAL METHODS OF DIAGNOSIS

Allen, L., and O'Brien, C. S. **Gonioscopy simplified by a contact prism.** *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 413-414.

The authors describe a plastic prism for gonioscopy supported by a speculum and adjusted by a small plastic handle. The portion of the prism that touches the eye is shaped to conform to the corneal curvature. A small film of methyl cellulose solution or of a saline solution separates the cornea from the prism surface. With the instrument inserted, the patient is seated before the slitlamp, and observations are made with the biomicroscope. The slitlamp is used for illumination. Different areas are examined by having the patient move the eye or by shifting the position of the prism with the handle. More than one fourth of the circumference of the chamber angle is visible with the prism in any one position. With experience it will be found that the entire examination time will correspond roughly to that needed for other examinations

with the slitlamp. None of the eyes examined showed any injury from the procedure. The prism has been left on the normal eye for as long as 20 minutes without disturbance of the tissues and without apparent discomfort to the patient.

John C. Long.

Apin, K. **The method and clinical significance of quantitative light-sense perimetry with Maggiore's projection perimeter.** *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 220.

Qualitative perimetry emphasizes the testing of the color sense of the retina which differs considerably in different parts of the retina. Quantitative perimetry is carried out only with colorless objects. It can be applied in two different ways: (1) the size of the test objects may be diminished step by step while the distance between the object and eye remains the same, (2) the size of the object may remain unchanged while the distance is gradually increased. With this method the retinal function is tested in a given area with an object that is just visible in that

area. Because of technical difficulties a combination of both procedures is usually used. For testing of the function of the retinal center Bjerrum's screen is very useful but not for testing of the retinal periphery. Maggiore's projection perimeter (Zeiss) meets the requirements better than a combination of common perimeters and Bjerrum's screen. The fundamental object of quantitative perimetry is to provide such differences in the size of the target at a given distance that a series of concentric isopters is obtained. In this way each retinal area is tested with the smallest visible stimulus in order to detect minimal disturbances of the retinal function. In order to get uniform test conditions examinations were carried out in a dark room illuminated only by indirect lights to provide uniformity of the contrast between object and perimeter. Shadowing of the perimeter arc has been eliminated. The projection perimeter permits rapid diminution of the object, and diminution of the contrast between object and perimeter arc. Whereas the ordinary procedure of perimetry often does not show any typical changes in such conditions as glaucoma, characteristic defects can be found by the use of the method outlined herein. For practical purposes this method of testing the retinal function can be highly recommended. Some case histories and a number of visual fields serve as illustrations of the text. (References.)

F. Nelson.

Klinger, Max. *Ophthalmologic examination in cranial trauma*. *Ophthalmologica*, 1945, v. 109, April-May, pp. 236-258.

The author emphasizes the importance of a thorough and systematic ophthalmologic examination after cra-

nial trauma, describes the different methods of investigation, and discusses the relations between the eye findings and the late pathologic consequences of the injuries. Changes of the external and internal eye muscles, variations in the retinal arterial pressure, decrease in corneal sensitivity, variations in visual acuity, fields, adaptations and color sense, often make it possible to confirm the organic origin of symptoms after brain injury and to localize a lesion in the mesencephalon, symptoms which often were considered functional and neurotic.

This essay is intended as a guide. The individual steps of the ophthalmologic study of a patient with a head injury are described in detail and their importance discussed. A plan is suggested which is based on extensive experience. Stages of the ophthalmologic examination are listed as follows:

1. History: general and ocular complaints with especial emphasis on diplopia and fatigability.
2. Examination of the anterior segment, particularly the pupillary reactions.
3. The disc, the retinal vessels, and the retinal arterial pressure.
4. Visual function, including visual acuity, accommodation, fusion, stereoscopic vision and color sense.
5. The motility, with patient standing and sitting (this is essential for testing the equilibrium) and analysis of nystagmus.
6. Extramacular visual function: perimetry and campimetry.

Fox, S. A. A new type of surgical peg. *Amer. Jour. Ophth.*, 1946, v. 29, May, pp. 586-587. (1 figure.)

Geis. Disintegration of cocaine. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 104.

Geis observed that cocaine-hydrochloride solutions, even if freshly prepared and not sterilized by heat, sometimes caused great irritation and even chemosis of the conjunctiva after instillation, like dionin. It is assumed that the drug had been kept too long in the pharmacy and that it had disintegrated into methyl alcohol, benzoic acid, and I-exgonin. The author suggests that cocaine might be entirely eliminated from the list of anesthetics in eye surgery. More stable substances such as pontocaine or novocaine could be substituted.

Hallett, J. W., and Pittler, S. Individually made acrylic moist-chamber spectacles and pinhole glasses. *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 725-728. (3 figures.)

Knight, H. C., and Schachat, W. S. Hyperpyrexia in treatment of ocular conditions due to syphilis. *Arch. of Ophth.*, 1946, v. 35, March, pp. 271-279.

The authors report 35 cases of syphilis of the eye in which specific anti-syphilitic chemotherapy, the usual local ophthalmic therapeutic measures, and the Kettering Hypertherm were employed.

Of 19 cases of syphilitic atrophy of the optic nerve, improvement resulted in four, or 21 percent; clinical progression of symptoms was arrested in seven, or 37 percent, and in six, or 32 percent, the disease either continued to progress or had its onset during Kettering Hypertherm treatment used in con-

junction with other (standard) methods of therapy.

In the treatment of syphilitic chorioiditis, this method of artificially induced fever therapy is valuable, particularly so when the lesions are fresh. It was employed in six patients who had acute chorioiditis; there was decided improvement in four, or 67 percent, and in the other two old quiescent lesions were present.

The method is especially valuable when employed in the treatment of the form of acute iritis that is associated with secondary syphilis and it affords a rapid form of treatment of this condition. Six cases of this type appeared in this series, and in each excellent therapeutic results were obtained.

The method is definitely beneficial in the treatment of syphilitic interstitial keratitis, and it is most helpful in alleviating the severe pain and photophobia which are often associated with this condition.

R. W. Danielson.

Leopold, I. H., and Nichols, A. Intraocular penetration of streptomycin following systemic and local administration. *Arch. of Ophth.*, 1946, v. 35, Jan., pp. 33-38.

A single intravenous or intramuscular injection of 10,000 units of streptomycin per kilogram of body weight produced detectable concentrations of streptomycin in the conjunctiva, sclera, extraocular muscles, and aqueous humor of the normal rabbit eye.

The concentrations in these tissues were increased by raising the systemic dose to 100,000 units per kilogram of body weight. With the larger systemic dose, streptomycin also appeared in the cornea, vitreous, chorioretinal tissue, and optic nerve of the normal rabbit eye.

Concentrations of streptomycin in

secondary aqueous humor were greatly increased over those in primary aqueous humor after streptomycin had been systemically administered, indicating selective action on inflamed areas.

Local administration of a solution of streptomycin containing either 5,000 or 50,000 units per cubic centimeter of isotonic solution of sodium chloride or of an ointment containing 5,000 units per gram of base failed to enter the aqueous humor of the rabbit eye with a normal cornea. However, both the solution and the ointment readily entered the aqueous humor of the rabbit eye with a partially abraded cornea.

High concentrations of streptomycin were noted in the aqueous humor of normal rabbit eyes after iontophoresis with a solution of streptomycin containing 5,000 units per cubic centimeter of an isotonic solution of sodium chloride for three minutes.

Methods of administration and doses for therapeutic purposes are suggested on the basis of these studies.

Mann, Ida. **A new synthetic mydriatic.** *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 8.

In a series of 58 patients, Mann presents the results of her experience in the use of a new synthetic mydriatic, dimethylaminoethyl benzilate ethochloride. She believes that it is a valuable substitute for the atropinelike drugs. It was used in four groups of patients: (1) as a mydriatic and cycloplegic for routine study and refractions; (2) for treatment of diseases for which atropine is generally used; (3) as a substitute for atropine when that drug was generally toxic; (4) in patients known to be sensitive to atropine and hyoscine and who had allergic eczema. It was shown to be equal or superior to

homatropine and hyoscine and suitable as a substitute for atropine.

Morris Kaplan.

Moreu, Angel. **The arsenoxides in the treatment of ocular syphilis.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, March, pp. 157-163.

The author discusses various aspects of the superiority of the arsenoxides, as typified by mapharsen, over salvarsan and neosalvarsan in the treatment of syphilis. After injection salvarsan must be converted to arsenoxide which is the active spirillicide. Arsenoxide is ten times less toxic in curative doses than are salvarsan and neosalvarsan. Nitritoid crises and liver damage do not occur with arsenoxide. The possibility of kidney damage, however, remains. Dosage and method of administration in 26 patients with ocular syphilis is given.

J. Wesley McKinney.

Murphey, P. J., and Schlossberg, L. **Eye replacement by acrylic maxillofacial prosthesis.** *The Military Surgeon*, 1945, v. 96, June, p. 469.

The various steps in the preparation of a prosthesis of acrylic material are described. Such prostheses have the following advantages: the natural contours of the face are restored; better matching of color is possible; stimulation of orbital tissues occurs by contact with the prosthesis; the acrylic material is only slightly susceptible to etching and can be repolished easily; the prosthesis is resistant to breakage. A number of pictures of the process of manufacture are included.

Robert N. Shaffer.

Riddell, W. J. B. **Clinical trial of a synthetic mydriatic.** *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 1.

Dimethylaminoethyl benzilate etho-

chloride is a promising synthetic mydriatic. In tests in which it was compared with atropine and with homatropine and cocaine for its mydriatic and cycloplegic action it proved to be an efficient substitute for homatropine but was neither so rapid nor so prolonged in action as atropine. There were no signs of sensitivity to it in those patients known to be sensitive to atropine. Two drops of a 1-percent solution were used. Morris Kaplan.

Roth, R. J. Detergents or wetting agents. *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 717-720. (2 figures, references.)

Ruedemann, A. D., and Glasser, Otto. Beta radiation in ophthalmology. *Cleveland Clinic Quart.*, 1946, v. 13, April, p. 104.

Beta radiation has been used by the authors in the treatment of corneal scars, recurrent pterygia, symblepharon and in a variety of lid conditions, including vernal catarrh, lid allergies, and papillomata. Stubborn chronic conjunctivitis and severe keratoconjunctivitis have responded well to this form of irradiation therapy.

A glass tube with radon in a small metal container provides the source of the beta emanations. This cylinder is applied to the cornea or lid, after topical anesthesia, at the end of a 35 cm. handle. There is only a 3-percent emission of the more deeply penetrating gamma rays. The lack of penetrability of the beta rays is demonstrated by the fact that superficial corneal scars responded better than more deeply situated opacities. In each instance, the reaction time was 14 to 21 days. The average number of treatments, for corneal scars, was seven. Benjamin Milder.

Rycroft, B. W. Sub-conjunctival penicillin and intraocular infection. *Brit. Jour. Ophth.*, 1945, v. 29, Oct., pp. 501-511.

A survey of experimental evidence regarding the route of administration of penicillin is given, and the following conclusions are summarized.

Direct intravenous injections of penicillin are the most effective means of obtaining high concentrations and bacteriostasis in the vitreous. A single injection of purified penicillin does little harm and will control incipient infection by susceptible organisms if given within 12 hours, and will maintain bacteriostasis for at least 24 hours. Multiple injections cause serious intraocular damage. Local applications of drops or ointment will not pass penicillin into the aqueous in normal eyes but do so where the cornea is inflamed or traumatized. Iontophoresis, constant corneal baths, and subconjunctival injections will maintain bacteriostatic levels in the aqueous, especially in the presence of inflammation. Intramuscular and intravitreous injections of penicillin do not produce bacteriostatic concentrations in the aqueous or vitreous and will not control experimental inflammation caused by organisms susceptible to penicillin.

Ten cases are reported in which subconjunctival injections of sodium penicillin in normal saline were made in hopelessly blind eyes which were to be removed. To prove that penicillin can reach the interior of the human eye in bacteriostatic amounts after subconjunctival injections, aspiration of the media was carried out after certain intervals of time, and the amount of penicillin present in the aqueous and vitreous was assayed. It was found that penicillin penetrated to the aqueous humor in seven of eight eyes after an

interval of 15 minutes. Assay of the vitreous was carried out in six eyes of which three showed bacteriostasis after 45 minutes. All amounts of penicillin detected in the aqueous or vitreous after subconjunctival injections were above bacteriostatic level.

Subconjunctival injections of 4,000 Oxford units of sodium penicillin will produce bacteriostasis of susceptible organisms in the aqueous humor of the human eye within half an hour of injection. It is probable that this occurs later in the vitreous humor and is likely to remain for at least 24 hours. Subconjunctival injection is a practical method of causing penicillin to reach the interior of the eye, and the earlier the injections are made, the better the results. Large doses should be employed not only because of the slow rate of diffusion but also to avoid the risk of producing penicillin resistance. (Bibliography.) Edna M. Reynolds.

Sorsby, Arnold. *Penicillin in ophthalmology*. Brit. Jour. Ophth., 1945, v. 29, Oct., pp. 511-536.

A complete review of the literature on the tolerance of the various ocular tissues for penicillin and the concentration of penicillin in the ocular tissues after various methods of administration is given. The literature regarding the use of penicillin in experimental infections and in clinical infections is also reviewed.

The marked difference in the sensitivity of different organisms to penicillin makes it seem that dosage is determined as much by the causal organism as by the patient's tolerance.

It has been established that high concentrations of the penicillin in current clinical use are not without deleterious effects on the cornea. Drops in a concentration of 2,500 units per

cubic centimeter are generally well tolerated. Subconjunctival injections of 500 to 600 units in 0.5 c.c. of water are well tolerated and can be repeated daily without much discomfort. Injections of 200 units of penicillin in 0.25 c.c. of isotonic saline solution into the anterior chamber is as much as it is justifiable to give. Injections into the vitreous are badly borne in dosages over 100 units.

There is lack of evidence that penicillin injected intramuscularly reaches the interior of the eye, but local use of penicillin by corneal bath, ionization, and subconjunctival injection give high concentrations of penicillin in the anterior segment of the eye. Experimental evidence does not indicate that these methods give any adequate concentration in the interior of the eye.

In the presence of corneal abrasion or ulcer, penicillin penetrates readily through the cornea into the anterior chamber. Intravitreal injection of penicillin in a grossly infected vitreous is justifiable, although experiments on the normal eye indicate that intravitreal injection must be practiced with extreme caution.

All the common causal organisms of ophthalmia neonatorum respond to the administration of penicillin in concentrations of 2,500 units per cubic centimeter. In blepharitis, paints containing 1,000 units per cubic centimeter are adequate.

Penicillin may soon replace the sulfonamides in treatment of the external infections of the eye. Systemic injection of the drug is not indicated, since it does not pass the blood-aqueous barrier and does not affect acute intraocular infections.

Clinical experience with penicillin in the treatment of trachoma is as yet too limited to permit any statement as to its value. It is generally assumed that

penicillin is ineffective against virus infections.

The use of penicillin in syphilitic infections of the eye would appear to be theoretically possible. (Bibliography.)

Scheie, H. G., and Hodes, P. J. **Injection of oxygen into Tenon's capsule.** Arch. of Ophth., 1946, v. 35, Jan., pp. 13-14. (See Section 16, Injuries.)

Thiel, R. **Testing and preservation of cutting qualities of surgical instruments.** Klin. M. f. Augenh., 1943, v. 109, Jan.-Feb., p. 89.

The customary methods of testing surgical instruments by cutting a hair or a membrane tightly stretched over a drum, are not satisfactory because such procedures are apt to damage the cutting edge. Thiel examines such instruments under a microscope instead. The sharpness of the point and the uniform configuration of the cutting edge as seen with strong magnifications give better evidence of the usefulness of the instrument, although it does not reveal much about the quality of the material. For the preservation of the sharpness of the cutting edge the methods of sterilization are of utmost importance. Sterilization in 95-percent alcohol followed by five seconds in live steam yielded the most disastrous results, whereas sterilization in hot air for 40 minutes never damaged the instrument noticeably. In order to avoid mechanical and chemical damage of the blade after use, it is kept in a specially constructed U-shaped metal holder. Damage of the blade through touch is practically impossible. Each instrument is kept and sterilized in its individual holder. After use the blade is never touched but is rinsed with normal saline solution and alcohol or ether to remove all traces of water. Then the

instrument is immersed in a solution of bone oil in ether, leaving a fine oily film on its surface which protects it absolutely from the influence of humid air. To remove this film it is sufficient to dip the instrument in ether for a moment before it is used for another operation.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Bietti, G. B., and Scano, A. **A study of the retinal circulation in the "black-out" of aviators.** Soc. Oft. Ital., 1943, v. 3, pp. 1-23.

The authors studied the retinal circulation experimentally with the Zeiss endoscope while in flight and confirm the opinion that "black-out" is the result of a disturbance of the relationship between intraocular pressure, pressure in the retinal arterioles and capillaries, and endocranial pressure. Normally, arterial pressure is higher than retinal pressure, which, in turn, is greater than endocranial pressure. In flying head-first, retinal pressure becomes higher than arterial or endocranial. In collapse, the arterial pressure falls below the endocranial, and in the latter two conditions vision may be lost, owing to failure of retinal circulation.

Similar symptoms were produced on the ground by means of varying pressure upon the globe. (7 illustrations.)

Eugene M. Blake.

Cowan, A. **Ocular imagery.** Arch. of Ophth., 1946, v. 35, Jan., pp. 42-44.

After a discussion of the advantages and disadvantages of the theory of collinear imagery, the author states that the aberrations of any optical system increase with the diameter of the aperture. With a small pupil there are less aberration and greater focal depth,

but less brightness; and if very small, even with adequate illumination, the beneficial effect of the narrow aperture is overcome by the diffraction at the edges. The pupil must be large enough to afford sufficient brightness and at the same time allow the formation of a sharp image.

Theoretically, the pupil must be neither too wide nor too narrow. The resolving power is fairly constant as long as the diameter is between 3 mm. and 5 mm., but particularly because of the peculiar nature of the eye as an optical instrument, a large pupil has little or no effect on the distinctness of the useful retinal image as long as the system is properly in focus, whether normally, by the accommodation, or by the aid of a lens. A small pupil serves its best purpose when the image is not sharply focused.

In ocular refraction the importance of the action of the pupil must not be overlooked. Only by the use of a cycloplegic can both the accommodation and the activity of the pupil be kept under control.

Since only a relatively small bundle of rays, close to the visual axis, forms the useful retinal image, it is often stated, and correctly, that with a large pupil the aberration a short distance from the axis sometimes seriously interferes with the results of retinoscopy. In most cases this fault can be eliminated by having the patient fixate the center of the mirror so that the examiner, disregarding the peripheral reflexes, can measure the error along the visual axis.

The closest approximation to the exact correction of ametropia should be the aim of the ophthalmologist; but his knowledge of physiologic optics will enable him not only to secure the best results but to know when further exact-

ness is superfluous. Perfection is neither possible nor necessary in an instrument so adaptable as the eye.

R. W. Danielson.

Csapody-Mocsy, Martha. *Test charts for women's needlework*. Klin. M. f. Augenh., 1943, v. 109, March-April, p. 251.

Needlework and reading are different tasks. The common test charts for close work did not contain any patterns of structures of woven or embroidered fabrics which would enable a person engaged in manufacturing or using such material to judge the amount of visual acuity necessary to reorganize and analyze the elements of the pattern or to find flaws in the weaving. The author undertook the task of designing test charts for women's eyes engaged in different textile work ranging from simple patterns made with rather rough material to the finest and most complicated designs for which very delicate threads are used. The patterns are printed in rows similar to reading charts. By the use of these charts the examiner is enabled to test workers, even illiterates, for their near vision, to determine which corrective lenses are required by the individual, and determine which person's eyes are particularly adapted for a certain type of textile work. (1 test chart.)

F. Nelson.

Easton, D. M. *Acetylcholine in the light and dark adapted frog retina*. Proc. Soc. Exper. Biol. and Med., 1945, v. 59, p. 31.

Extraction of frog retinas in acidified Ringer solution reveals an average acetylcholine content of 3.4 gamma/gm. in light-adapted and 3.6 gamma/gm. in dark-adapted frogs. Direct comparison of acetylcholine activity in extracts of

light- and dark-adapted retinas, without reference to absolute magnitudes, also reveals no difference greater than the error of the method. The lack of significant difference is in accord with the work of Therman, but not with that of Lange, who finds a tenfold increase upon dark adaptation. The range of experimental error of the assay method is no less than 10 percent, even under the best conditions, and a difference of such magnitude might very well be of physiologic significance.

Robert N. Shaffer.

Eggers, H. Refraction by the astigmatic eye. *Arch. of Ophth.*, 1946, v. 35, April, pp. 346-353.

The contours of an astigmatic beam of light are described. A formula is given for the determination of the circle of least confusion in the interval of Sturm. In a practical refraction, one attempts to eliminate the interval of Sturm by making the two focal points of the principal meridians coincide. In cases in which a full correction of the astigmatism cannot be tolerated, one should first reduce the interval of Sturm, and with it the size of the circle of least confusion, by a partial correction of the cylindric error. Then the position of the reduced astigmatic interval is shifted by means of spherical correction so as to bring the circle of least confusion on the retina. The amount of spherical power required is half the dioptric value of the remaining uncorrected astigmatism. A similar procedure was recommended by Copeland who stated that "if the cylinder is reduced a change must be made in the spherical element of the lens. In reducing the cylindric element of any correction add half of the amount of the reduction to the sphere."

John C. Long.

Elliott, A. J. Significance of aniseikonia in aviation. *Arch. of Ophth.*, 1946, v. 35, April, pp. 354-360.

The relationship of aniseikonia to flying performance in the landing of aircraft was investigated in two selected groups of the Royal Canadian Air Force. In the first group there were 175 trainees who had ceased training because of difficulties in landing and in the second group there were 50 experienced pilots. The amounts of aniseikonia were found to be very small in each group, and no practical correlation with landing performance could be ascertained.

A series of landings was made in order to study the practical effect of various aniseikonic lenses on flying performance during landing. It was noted that when monocular visual clues predominated the flying performance was not affected by the anomalous binocular clues produced by wearing aniseikonic lenses.

Fishenden, R. B. Types, paper, and printing in relation to eyestrain. *Brit. Jour. Ophth.*, 1946, v. 30, Jan., p. 20. (See Section 18, Hygiene, sociology, and history.)

Fletcher, R. J. Presbyopic additions. *The Optician*, 1946, v. 61, April 26, pp. 245-246.

Amplitude of accommodation falls fairly rapidly between the ages of 45 and 50 years. Textbook table additions are often too high for the patient's comfort. A patient should have one half to one third of his reserve accommodation uncorrected. A table is presented that reveals the amplitude of accommodation and the addition necessary for varying distances, for example, desk work, based on measurements in 300 patients.

I. E. Gaynon.

Gescher, J. A new arrangement for the objective measurement of dark adaptation. *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 99.

Following Rieken's advice to use optokinetic nystagmus as an objective test for dark adaptation the author developed an arrangement of apparatus which allows exact registration of the process of dark adaptation and subsequent transposition of the data into the Engelking-Hartung adaptation curve. On a Cord nystagmus drum, placed 30 cm. in front of the patient's eyes, a light circle, 10 cm. in diameter, is projected with a Hess hammer lamp that is adjusted at the patient's right side and a little behind him. By means of two rheostats, the light intensity reflected from the illuminated spot on the drum can be regulated and registered exactly. The beginning and disappearance of optokinetic nystagmus can be observed easily and accurately with the help of the Zeiss corneal microscope which is equipped with a lamp which projects a spot of blue light three millimeters in diameter, onto the sclera. The whole apparatus is first tested and adjusted by examining a person with a normal adaptation curve. Uncertain subjective factors are eliminated. The objective test is more accurate and less time consuming than any subjective examination. (References.) F. Nelson.

Göthlin, Gustaf F. The fundamental color sensations in man's color sense. *Kungl. Svenska Vetenskapsakademiens Handlingar*, 1943, 3rd series, v. 20, no. 7.

The author presents an extensive treatise in which he describes his method of using the liminosspectroscope for measuring the monochromatic radiations within a spectral region. His work on the monochromatic radiations of

wave length 460, 455, 450, 445, 440, 435, and 430 mμ in the indigo region of the spectrum leads him to believe that blue is a fundamental color and that violet and indigo arise from the fusion of blue and red receptors. The zone of pure yellow never exceeded two mμ in the spectrum and its position varied much in the subjects tested. The fact that the color discrimination of maximum yellow revealed a minimum in pure red and pure green, leads the author to believe that a person with normal color vision need have no special receptors for yellow. Hence, the fundamental hues of the human color sense are red, green, and blue. A review of the present status of color receptors is given. The sensation of white is a synthesis in two stages: stimulation of red and green produces yellow, and yellow and blue produce white. (21 figures, references.) I. E. Gaynon.

Grieve, John. Incidence of defective colour vision. *Nature*, 1946, v. 157, March 23, p. 376.

The usually reported incidence of defective color vision in males is seven to eight percent. This paper reports an incidence of 6.63 percent, in a survey of 16,000 Royal Air Force candidates. Ishihara charts were used in daylight, and if the individual failed to pass this test, the Giles-Archer Colour Perception Unit (not described) was used. The individual was considered to be normal if the latter test was performed without error. The results are in harmony with previous reports.

Benjamin Milder.

Halstead, W. C. Chronic intermittent anoxia and impairment of peripheral vision. *Science*, 1945, v. 101, June 15, p. 615.

Twenty male subjects selected to

meet the standards of the Service Air Corps were exposed in a low-pressure chamber to a simulated altitude of 10,000 ft. above sea level for five or six hours per day, six days a week, for four or five weeks. During the third and fourth week, 13 of the 20 subjects developed a marked and progressive impairment of peripheral vision. The subjects were not aware of this loss. It could not be immediately relieved by inhaling pure oxygen. In some cases days or weeks elapsed before a return to normal visual efficiency occurred. In some of the cases central vision also was temporarily impaired.

Four other subjects were similarly exposed to altitudes ranging from 11,500 to 18,000 ft. In them the impairment of peripheral vision appeared earlier, was more marked, and normal vision was recovered more slowly. The cortex of the frontal lobes of the brain is the probable region whose involvement produces this peripheral loss in visual function. Robert N. Shaffer.

Hamburger, F. A. **Monocular dominance in binocular vision.** *Klin. M. f. Augenh.*, 1943, v. 109, Jan.-Feb., p. 1.

Even in eyes with identical visual acuity and equal refraction, one eye is often dominant over the other. Sometimes even an eye with lesser visual acuity is dominant. However, dominance of one eye is not always constant. For perfect binocular vision it is desirable not only to have both eyes equal in their monocular performance but also that a minimum of dominance of one eye over the other is either present in the beginning or acquired by practice. As consultant Navy ophthalmologist in charge of a range-finder training school, the author examined two selected groups of participants of separate classes. All the men had per-

fect vision in both eyes, and faultless binocular vision and depth perception. For determination of dominance, Hamburger used a simple pencil-light test, once before the training course started and once upon graduation. About one third of the men tested showed dominance of the right eye in the beginning, but it was found in only 15 percent at the end of the training period. Less than one percent had a dominant left eye in the first test, less than 0.5 percent in the second test. The author attributes the disappearance of dominance to the training of binocular vision in range finding. It is his opinion that dominance of one eye is the equivalent of neglect or a latent tendency to amblyopia of the other. Apparently there is no connection between dominance and "handedness." Not a single man was left handed. The relative inferiority of one eye, usually the left, may be influenced to a certain extent by habitually neglecting it in bodily postures and movements such as, for instance, the use of the right eye more than the left in the aiming of a gun.

F. Nelson.

Handman, M. Sr. **Familial paresis of accommodation.** *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 186.

The patient had had difficulty in reading since she was a small child and used her mother's reading glasses. She also was night blind. Her mother had glaucoma simplex and coronary cataract. The patient was seen when she was 18 years of age and had a manifest hypermetropia of 0.5D. Twelve years later her accommodation was almost zero. She also had coronary cataract. She had no children. One of the patient's sisters had five children of whom one daughter had an accommodation of only 5.0D. when 23 years of age,

another daughter only 1.0D., and one son 2.0D. in each eye. The other children had no pronounced abnormality of accommodation. Disturbances of the pupillary reactions were not observed. The lesion was probably hereditary and caused by an early degeneration of the nucleus for accommodation below the aqueduct of Sylvius. F. Nelson.

Hardy, L. H., Rand, G., and Rittler, M. C. Tests for the detection and analysis of color blindness. *Arch. of Ophth.*, 1946, v. 35, March, pp. 251-270.

The authors conclude that the Rabkin test, when used with care in administration, scoring, and interpretation, yields much more information concerning the type of defect of the examinee than does, for example, the Ishihara test or the American Optical Company test. As the result of their study of the test, the authors recommend changes in scoring certain of the plates; a revised procedure for classifying the type of defect in red-green vision is described, and constructive comments are offered for the improvement of some of the plates. In addition, the following general conclusions concerning the second edition of the Rabkin test seem justified.

When properly administered, the test affords a good device for screening the subject with defective color vision from the subject with normal color vision if 75 is taken as the critical performance score.

No analysis as to type or extent of defect can be based on the score alone.

The test taken as a whole affords an excellent means of classifying red-green dichromasy into the two groups (protanopia and deuteranopia), and of classifying red-green anomalous trichromasy into the two groups (deuteranomaly and protanomaly).

The test as now constructed is, however, not adequate to differentiate anomalous trichromasy and dichromasy. R. W. Danielson.

Heinsius, E., and Hamburger, F. A. The comparability of measurements of dark adaptation and twilight vision. *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 204.

In modern warfare it is no longer enough to eliminate men with hemeralopia from combat teams. It is necessary to select from a large number of soldiers those who have the best night vision. Optimal requirements are (1) shortest possible adaptation time, (2) low threshold after completed adaptation, (3) high visual acuity in minimal illumination, (4) relative insensibility to dazzling. It is not certain that these four qualities can be found together in one particular eye. Three instruments for measurement have been available: the Engelking-Hartung adaptometer, Comberg's nyctometer, and the Nowak-Wetthauer apparatus. Because electric current upon which the instruments depend is variable, absolute values cannot be obtained. It is also difficult to manufacture the necessary light filters uniformly, so that their light-absorptive qualities are identical. Consequently measurements are not absolutely comparable, even with the same apparatus, much less with different ones. The Nowak-Wetthauer apparatus is best suited for these examinations and will be perfect after it has been equipped with a current regulator. (1 figure, 6 charts, references.) F. Nelson.

Herzau, W. Horror fusionis and aniseikonia after trauma. *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 193.

An army officer, 40 years of age,

had been wounded by a shell splinter in the face and right antrum that resulted in concussion of the right eye with concentric choroidal rupture and pupillary paresis. Vision in that eye was reduced to 5/10; the other eye was normal. Double vision was noticed after the trauma. The images were uncomfortably close together. There was a manifest divergence of two degrees in the primary position that increased in looking up and to the side. It was absent when looking down. It was assumed that the exophoria was present before the injury. The images of the injured right eye appeared considerably smaller and blurred. Horopter apparatus and metroscope could not be used to determine aniseikonia. Size lenses were not available. As substitutes twin lenses were used with the help of which the diplopia disappeared when the patient looked straight forward into distance. With pinhole the same effect was obtained immediately. A special lens was ground to compensate for the 13-percent size-difference of the images. With this correction parallel position of the eyes and binocular single vision resulted only when patient looked straight forward. For the right eye a diaphragm with two holes was given, a central 4-mm. hole for distance and another below and nasally for reading. This correction relieved the disturbance.

Hirsch, M. H. **Relation of visual acuity to myopia.** *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp 418-422

Visual acuity and the degree of myopia were determined in 64 eyes. The myopia ranged from 0.50 to 13.50 D. The visual acuity decreased in an orderly fashion as the degree of myopia increased. Plotting the logarithm of visual acuity on the logarithm of the

degree of myopia gives a coefficient of correlation of +0.95. Confidence limits were determined for the regression lines and tables set up for predicting either the degree of myopia or the visual acuity when the other is known. The data presented would be of value in refraction in guarding against an overcorrection of the myopia and also in the detection of malingering.

John C. Long.

Junker, H. **Monjé's test for stereopsis.** *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 239.

Monjé's new apparatus, devised to measure depth perception, was used for the screening of Navy personnel in a range-finder school for naval artilleryists. The task was to eliminate the influence of the displacement of the physiologic middle or zero position of the central one of three threads in contrast to its physical zero position. This phenomenon had been observed by Monjé in 58 percent of all persons tested by him. With the Monjé apparatus which exploits this observation it is now possible to select the persons who possess a perfect depth perception and are fit for training in range finding. (References.)

Martin, D. H. H. **Some refinements in cross-cylinder technique.** *The Optician*, 1946, v. 111, May 17, pp. 307-310.

When using the cross-cylinder, the sphere in the trial frame should be adjusted with each change of the power of the cylinder but not of its axis. During the test hypermetropia is undercorrected and myopia overcorrected less than 0.50 D. The size of the test letters used should be small enough to be legible to the patient on either side and yet with the cross-cylinder in either position to show a change on reversal of the

cross-cylinder. When vision is 6/4 or better a 0.12D cross-cylinder should be used, between 6/5 and 6/10 a .25D cross-cylinder, and when it is less than 6/12, a 0.50D cross-cylinder. The position of the axis of a cylinder should be determined before ascertaining its power, and then the power should be checked until there is equality in either position.

McFarland, R. A., Halperin, M. H., and Niven, J. I. **Visual threshold as an index of physiological imbalance during insulin hypoglycemia.** *Amer. Jour. Physiol.*, 1946, v. 145, Jan., pp. 299-313.

In order to measure the effects of disturbances in oxidative metabolism, the writers investigated the changes in the thresholds of the foveal differential discrimination of light intensity caused by insulin hypoglycemia in four human subjects. The insulin was administered intravenously. A rise in the visual thresholds is produced if the capillary blood sugar drops below 65-70 mgm. percent. The inhalation of 100-percent oxygen results in a reversal of a large part of the impairment caused by hypoglycemia. The effect of hypoglycemia on vision is probably due to an impairment of the oxidative processes in the nervous tissues.

Melchior Lombardo.

McKay-Ferguson, Orlig. **Notes on letter acuity.** *The Optician*, 1946, v. 61, April 26, pp. 248-252.

The determination of letter acuity is perhaps the most simple and yet most significant item in any preliminary subjective examination. The letter "B" is the hardest to recognize. The following letters are recognized, the first most easily and the following with increasing difficulty: L, T, V, C, O, Y, P, F, D, Z, N, E, R, S, G, and B. Other sig-

nificant factors in visual acuity are the resolving power of the eye, aligning power, amount of accurate fixation, pupil size, and degree of contrast.

I. E. Gaynon.

McKay-Ferguson, Orlig. **The coating of optical surfaces.** *The Optician*, 1946, v. 61, March 1, pp. 83-84, 103-104.

The new technique to minimize surface reflection and increase light transmission is discussed. The amount of Fresnel reflection may be calculated if the angle of incidence of the beam and the refractive indices of the two media are known. A considerable amount of light is reflected and lost in ophthalmic instruments. If both sides of the lens are coated, the reflected rays will become neutralized by reflective interference. The energy is not destroyed and augments the amount of light transmitted by refraction. Methods for producing the coating are described.

Pascal, J. I. **Astigmatism and the accommodative unit.** *The Optician*, v. 111, May 10, p. 285.

The astigmatic correction at near is always a little different from the astigmatic correction found at distance. An accommodative unit is the amount of accommodation necessary at one meter. In the ametropic eye the diopter, used as a unit, is either too large or too small. Using the formula $U = 1 + \frac{2}{dL}$, in which U is the accommodative unit, L is the correcting lens, and d is the distance in meters between the correcting lens and the principal plane of the eye, a different refractive status

of the principal meridians may be calculated. As the two principal meridians have different accommodative units, the difference between these two creates the difference in astigmatism at near.

I. E. Gaynon.

Podestà, Hans. **The systematic scientific structure of the color body.** Klin. M. f. Augenh., 1941, Supplement.

In this monograph the author reviews the development of the science of the color sense. The theories concerning the origin of colors, the function of normal and abnormal color perception including a study of the ontogenesis and phylogenesis of the color sense are discussed. The purpose of this little book (60 pages) is to familiarize the ophthalmologist with the simplest fundamentals of the conception and laws of this branch of science and to give a continuous presentation of the elementary facts of the psychologic foundations. The structure of the total color continuum in which the various relations between the color sensations are arranged according to subjective (psychologic) absorption of objective (external) color stimuli is illustrated symbolically in schematic stereometric pattern. Its geometric construction is only alluded to briefly. (14 figures, references.)

F. Nelson.

Rieken, H. **Objective examination for nyctalopia with makeshift apparatus.** Klin. M. f. Augenh., 1943, v. 109, March-April, p. 197.

In previous papers Rieken demonstrated the usefulness of optokinetic nystagmus for testing dark adaptation. For tests under primitive conditions the author recommends the following procedures. Strips of commercially manufactured luminescent paper are cut in various widths and

pasted vertically on a dark band made of fabric or paper, leaving dark spaces between the luminescent strips. The band is either put around a drum or cylinder which can be rotated about a vertical axis by means of a simple mechanism over two parallel cylinders that rotate synchronously. The latter provides a larger optokinetic stimulating surface. The optokinetic nystagmus that is induced in a dark room can be observed by means of a simple electric ophthalmoscope, the light bulb of which is dimmed with a blue glass filter. Illumination of the pupil should be avoided in order to eliminate the disturbing interference of the light cone of the ophthalmoscope. The apparatus is well suited for orientation tests and to eliminate malingering. (2 figures, references.)

F. Nelson.

Silva, Daniel. **Optic theory of contact lenses.** Bol. del Hosp. Oft. de Nuestra Señora de la Luz, 1946, v. 3, Jan.-April, pp. 131-142.

With illustrations and graphs, the author discusses optical principles of contact lenses, and leads up to the following conclusions: Forming a continuous optical system with the eye itself, the contact lens avoids the disturbances produced by the distance factor between constituent parts of the ordinary spectacle system, prevents secondary images and distortions, and avoids anisometropia. W. H. Crisp.

Stevens, D. M., **Relation between dark adaptation and age.** Nature, 1946, v. 157, March 23, p. 377.

Night vision is worse in the aged, because the changes of senility produce a yellowing of the ocular media. In measuring the dark-adapted visual threshold with the Wald-Stevens Adaptometer, in nutritional surveys, it was

found that there was a progressive rise in the threshold with increasing age. It is concluded, therefore, that dark-adaptation tests based on a normal range of dark adaptation in healthy persons are less sensitive for detecting pathologic states in older individuals, and a correction factor should be applied in evaluating such tests in persons over the age of 30 years.

Benjamin Milder.

Wald, George, *Human vision and the spectrum*. Science, 1945, v. 101, June 29, p. 653.

The author discusses the physiology of light perception by the retina. His investigations confirm previous measurements on the spectral sensitivity of foveal cones and of rods well outside the macula. In addition, he has measured the sensitivities of peripheral cones by calculating the differential between the data found in a light- and dark-adapted eye. The differences in sensitivity of central and peripheral cones, and of normal and aphakic eyes yield estimates of the absorption of light by the macular pigment and by the lens. The pigment of the human macula has also been extracted and certain of its optical and chemical properties have been examined directly. The analytical data are too detailed and technical to summarize satisfactorily.

Of clinical interest is the amazing increase in sensitivity in the violet and ultraviolet portion of the spectrum in the aphakic eye due to the loss of the filtering process of the yellow lens. In illumination in the region of 365 μ , the average increase in sensitivity amounts to 1,000 times that of the normal eye. The author has seen patients with aphakic eyes read a Snellen chart that he was unable to see in this illumination.

OCULAR MOVEMENTS

Apin, K. *Constructive procedures to combat strabismus in Latvia and the result of this campaign*. Klin. M. f. Augenh., 1943, v. 109, Jan.-Feb., p. 63.

Worth stated that in 93.1 percent of all patients strabismus starts before the sixth year of life but only 6.1 percent of them appear for treatment at or before that time. There are various reasons for this deplorable but undeniable delay. Among them are: Insufficient enlightenment of the laymen and the ignorance of many general practitioners and ophthalmologists of the importance of early conservative treatment of the very young child in whom the amblyopia can be prevented and good binocular vision can be established. Apin started an intensive campaign in Latvia directed against lack of proper knowledge and interest among physicians. Pamphlets and posters were distributed and exhibited, and articles published in the daily press and in magazines. The work was gradually expanded and intensified over a period of many years. Systematic examination of school children, and later also of children of preschool age, in kindergarten and nursery, was introduced. The success of this campaign soon became noticeable though much that was desirable remained to be done. Reported statistical data relating to 1,981 cases of strabismus of all age groups seen between 1922 and 1940 are analyzed. Though the number of children between the first and fifth year of life

was still relatively small at the time of this publication (10.6 percent) it was at least considerably higher than at the beginning of the campaign (1.3 percent). Lack of understanding and perseverance in conservative functional treatment still represented the most important handicap. Most patients or their parents were predominantly interested in the elimination of the cosmetic aspect of strabismus, not in functional prophylaxis and rehabilitation. Many patients never returned after the first consultation. Among the comparatively small number of patients who were willing to carry on with the methodical conservative therapy, a rather high percentage showed improvement of amblyopia. Unfortunately, only 10 of the 1,981 patients were below the age of six years when first seen. The vast majority came so late that only moderate improvement could be expected. The program as a whole shows the importance of enlightenment and education as the predominant factors in the important struggle directed toward saving the function of the eyes of the four percent of the total population who have strabismus.

Bietti, G. B., and Scano, A. The effect of anoxia upon ocular movements. *Trans. Soc. Oft. Ital.*, Rome, 1943, v. 3, pp. 1-11.

In an atmosphere corresponding to an altitude of 5,800 to 8,000 meters there was slowing of ocular movements and increased difficulty in reading, which reached a point 218 percent of normal. Fixation required a longer time, and the number of fixation periods in reading increased. Attention and comprehension were greatly retarded. The picture is very much like that observed in the study of ocular fatigue.

Eugene M. Blake.

Bucker, C. W. Seesaw nystagmus associated with choroiditis and positive neutralization test for toxoplasma. *Arch. of Ophth.*, 146, p. 35, March, pp. 301-302.

Nystagmus in which one eye turns rhythmically up and down while its fellow moves contrarily, in the nature of a seesaw, is strange and rare. The only case that Rucker has been able to find in the literature is one reported in 1914 by Maddox.

This case occurred in a white man, aged 51 years, who had come to the Mayo Clinic on October 11, 1944, complaining of loss of vision. He had been myopic since childhood and had worn glasses for thirty years.

His present difficulty began four years before admission, when he noted failure in his vision. Two years later further deterioration had occurred in the visual acuity, and about that time he had blisters on his lips for several months. One year before his admission his eyes began to jump. For six months before admission he had had a humming tinnitus.

On examination at the clinic the visual acuity was recorded as 2/60 in the right eye and 3/60 in the left eye. There was a constant seesaw nystagmus. As the right eye turned up, the left turned down; and as the right turned down, the left turned up. The rate was 128 beats per minute, and the movement covered a distance of approximately one millimeter.

Examination disclosed the following: there was myopia of 4D., the entire choroid of both eyes appeared to be sclerotic and finely mottled with pigment, the retinal arterioles were greatly attenuated, and the fields of vision were restricted to small islands.

All laboratory examinations were negative except that a specimen of the

patient's blood produced a slight to moderate neutralization against the organism *Toxoplasma*.

To account for disturbed pupillary reflexes and disjunctive nystagmus a lesion in the brain would be expected to involve the midbrain and pons. Attempting to name the implicated fiber bundles at present leads into the field of speculation. R. W. Danielson.

Chamlin, M. **Oculomotor paralysis with partial recovery.** Arch. of Ophth., 1946, v. 35, Jan., pp. 23-27.

A case of internal and external ophthalmoplegia due to paralysis of the third nerve is described.

Because of the internal ophthalmoplegia, an opportunity was afforded to study the effects of various drugs on the pupil during the paretic stage as well as during partial recovery. The reactions observed fit well into the present-day concept of the mode of action of the cholinergic and adrenergic drugs.

Although there was no increase in tension, the reaction to physostigmine resembles that of a glaucomatous eye.

The "pseudo-Graefe" phenomenon seen in the stage of recovery of paralysis of the third nerve is illustrated. This retraction of the paretic lid can be produced by having the patient attempt to look in directions other than the classic "down and in."

R. W. Danielson.

Donahue, H. C. **Complications of herpes zoster ophthalmicus.** Amer. Jour. Ophth., 1946, v. 29, May, pp. 582-585. (See Section 14, Eyelids and lacrimal apparatus.)

Feigenbaum, A., and Kornblueth, W. **Paralysis of convergence with bilateral ring scotoma following injury to oc-**

cipital region. Arch. of Ophth., 1946, v. 35, March, pp. 218-226.

A case of convergence paralysis after trauma in the occipital region is described. Accommodation and the near-point reaction ("convergence reaction") of the pupils were intact; the independence of the near-point reaction of accommodation and of convergence is once more stressed. The localization of the supranuclear convergence centers in the occipital region of the brain near the visual cortex is confirmed.

A remarkable finding in the field of vision of both eyes was a persistent, though inconstant, ring scotoma. Fatigability, caused by general damage to the striate areas, is assumed to be the basis of this disturbance in the fields, which is fairly regularly associated with an injury to the occipital region of the head. Ferree, C. E., and Rand, G. **Examination of ocular aptitude and of ocular and general fatigue in aviators.** Arch. d'Ophth., 1945, v. 5, no. 3, p. 297.

The authors describe an instrument known as a tachytoscope designed for the purpose of testing visual aptitude, particularly in skilled machine workers and aviators. Ordinary ophthalmologic tests completely ignore the important factors of accommodation speed, convergence and divergence facility, and oculomotor adaptation in the different directions of gaze. The authors stress that general nervous fatigue is readily recognized by its effect on eye function. The instrument allows a series of tests to be made and provides a performance curve of the results which can become a permanent part of the individual's record. In addition to its function in detecting oculomotor abnormalities, the instrument can also be

used for training, in the presence of oculomotor deficiencies.

Phillips Thygeson.

Grieve, John. Relative incidence of sternomastoid and ocular torticollis in aircrew recruits. *Brit. Jour. Surg.*, 1946, v. 33, Jan., p. 285.

The author found 16 cases of ocular torticollis, characterized by a head tilt associated with hyperphoria (or hypertropia), in a survey of 9,500 aviation recruits. In this group there were only two persons with sternomastoid torticollis and none with spastic torticollis.

The differential diagnosis of ocular and sternomastoid torticollis is discussed briefly. The latter is characterized by facial asymmetry, and a contracted sternomastoid muscle, and resistance to passive straightening. The face looks away from the side of the head tilt and the ocular-muscle balance is normal. In the ocular type, a vertical-ocular-muscle imbalance is always present, conjugate ocular movements are affected, the face looks toward the side of the head tilt, and passive straightening of the head is possible.

As evidence of the prevailing tendency to disregard ocular-muscle imbalance in the diagnosis of torticollis, the author cites statistics from an orthopedic hospital which reported 108 cases of sternomastoid torticollis, as opposed to two eye hospitals which reported 33 cases of ocular torticollis and only two of the sternomastoid type.

In the absence of a readily demonstrated sternomastoid contraction, the ocular muscles must be studied carefully.

193. (See Section 3, Physiologic optics, refraction, and color vision.)

Kirby, D. B. Paralysis of ocular elevation with and without ptosis. *Arch. of Ophth.*, 1946, v. 35, March, pp. 199-217.

The conditions of paralysis of ocular elevation with and without ptosis are described, and various cases illustrating the different types (based on the muscle that is paralyzed) are reported. The purpose of the paper is to clarify the indication for, and the technique of surgical procedures which may be useful in correcting the heterotropia and the ptosis. The heterotropia manifests itself as a hypotropia of the paretic eye or a hypertropia of the sound eye that develops when the paretic eye prefers to fixate. A differentiation is made between real ptosis and pseudoptosis.

The following conditions are evaluated from the surgical standpoint: (1) paralysis of the superior rectus muscle alone, (2) paralysis of the inferior oblique muscle alone, (3) unilateral paralysis of the superior rectus and inferior oblique muscles, (4) bilateral paralysis of both superior rectus and inferior oblique muscles, and (5) bilateral complete external ophthalmoplegia. In all these conditions the association of ptosis is considered. The surgical correction that is possible; the procedures that are feasible, and the methods used in applying the principles of reconstructive surgery to these conditions and the actual results obtained in the cases reported are described.

James W. White, in discussion, records seven case reports.

Mann, Ida. Exophthalmic ophthalmoplegia and its relation to thyro-

toxicosis. *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 645-654. (See Section 13, Eyeball and orbit.)

Morgan, G. E. *Amblyopia ex anopsia in the Armed Forces.* *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 713-717. (References.)

Papoleczy, E. *The congenital and hereditary paresis of eye muscles.* *Klin. M. f. Augenh.*, 1943, v. 100, Jan.-Feb., p. 77.

Two cases of congenital ophthalmoplegia are reported. A man aged 20 years, whose eyes had been paralyzed since birth, was highly myopic and amblyopic in both eyes. All eye movements were absent, and he had divergent strabismus and rotary nystagmus in the left eye. In each eye the fundus was normal except for a temporal conus. He was left-handed. A neurologic examination was negative, and there was no indication that the anomaly was hereditary.

In a woman, aged 19 years, both eyes were paralyzed since birth. She had bilateral ptosis and moderate myopic astigmatism and amblyopia in both eyes. Both superior rectus muscles were completely paralyzed, and the external and internal rectus muscle was partially paralyzed in each eye. There were no neurologic findings. The patient's father, one sister, and two brothers have a similar condition. It is assumed that these anomalies of development are produced by pressure of the fluid in the primary vesicle of the embryonic brain during the fourth or fifth week of fetal life. The nuclei of the nerves which innervate the levator of the upper lid and the superior rectus muscle, the muscles which are paralyzed most frequently, are particularly exposed to this pressure. F. Nelson.

Rebello Machado, Nicolino. *Heterophorias.* *Rev. Brasileira de Oft.*, 1946, v. 4, March, pp. 195-224.

This 29-page general discussion of the subject is accompanied by description of various classical tests and a brief outline of treatment. (8 figures, references.) W. H. Crisp.

Redlich, F. C., Callahan, A., and Schmedtje, J. F. *Electrical potentials from eye movements.* *Yale Jour. Biol. and Med.*, 1946, v. 18, March, p. 269.

Previous investigators who used frontal skin leads on the electroencephalograph have demonstrated changes in electric potential during blinking and other lid movements. These "blink waves" have been considered to be due to a potential difference between the cornea and retina. They are greatest when the optic axis is aligned with the leads, and disappear completely when the retina is destroyed, or after evisceration or enucleation.

A study of variations in potential, during blinking, ocular movements, and pressure on the bulb, was made in 40 patients who had a variety of ocular conditions. The "blink waves" varied with the frequency and strength of blinking; they were not affected by disease of the retina or optic nerve (even when there was no light perception); but they were abolished in evisceration and enucleation. Pressure on a normal globe produced a similar electrical discharge.

No explanation of the source of the corneo-retinal potential is offered.

Benjamin Milder.

Spiegel, E. A., and Scala, N. P. *Changes in labyrinthine excitability in lesions of optic tract or external geniculate body.* *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 408-410.

Lesions of the optic tract or of the external geniculate body were produced electrolytically in cats or the optic tract was cut. Following these operations a marked difference was noted between the postrotatory nystagmus following clockwise rotation and that following counterclockwise rotation. The postrotatory nystagmoid movements toward the side operated upon lasted up to three times as long as those toward the normal side, and there were as many as four times as many jerks. These observations seem to indicate that impulses from the homolateral halves of the retinas have an inhibitory effect on vestibular-ocular reflexes that produce nystagmus to the same side. (2 illustrations.)

John C. Long.

Swann, L. A. **Comments on the cover test.** *The Optician*, 1946, v. 110, Jan. 18, pp. 451-453.

The cover test reveals the speed of fusion recovery. Three conditions of recovery are met; namely, quick or slow recovery, and apparent latency (no movement). The test can be applied in any part of the motor field and can be used to determine the near point of convergence objectively and subjectively.

CONJUNCTIVA

Allen, J. H., and Erdman, G. L. **Meningococcic keratoconjunctivitis.** *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 721-723. (1 table, references.)

Alvarez, Abundio. **Bulbar vernal conjunctivitis and its relation to allergies.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, pp. 185-199.

The clinical and pathologic picture

of a limbal type of vernal conjunctivitis is presented. The allergic character of the condition seems established.

J. Wesley McKinney.

Lewis, P. M. **Penicillin in gonococic conjunctivitis; its use in 30 cases, compared with the sulfonamides in 173 cases.** *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 694-698. (3 tables, references.)

Magitot, A. **Allergic conjunctivitis and keratitis.** *Ann. d'Ocul.*, 1945, v. 178, Aug., pp. 321-334.

In this comprehensive outline allergies are classified according to: (1) the physical or chemical nature of the allergen; (2) the places of contact; (3) the time of origin, whether congenital or acquired.

The effect of histamine is illustrated by Bruce's experiment in which the application of oil of mustard is without irritative reaction if the conjunctiva is previously anesthetized with cocaine. In gonococcal iritis pain is decreased and healing increased after alcohol injection of the ciliary ganglion. The phenomenon of Wessely illustrates the allergic character of interstitial keratitis: a corneal reaction very similar to interstitial keratitis in one eye follows a heterogenous corneal serum injection into the other eye if the first eye has been sensitized by a similar corneal injection two weeks previously. The success of keratoplasties depends partly upon allergic reactions; a larger proportion of failures follows pneumococcal and streptococcal infections.

Conjunctival allergies may be divided into four groups:

1. Acute, often associated with conjunctival eosinophilia, positive Prausnitz-Küstner test and negative patch tests.

2. Subacute or follicular reactions,

which include reactions to drugs, in which cutaneous and Prausnitz-Küstner tests may be negative.

3. Purely ocular reactions associated with follicular hypertrophy after contact with pollens, animal and bacterial products, and cosmetics. Spring catarrh is included in this group and its relation to endocrine dysfunction and vasosympathetic sensibility is mentioned. There are hundreds of allergens.

4. Infectious allergies. Staphylococcal allergies are classified into hemolytic and nonhemolytic of which the latter are found in styes and similar infections, the former, in chronic blepharoconjunctivitis, and this is frequently associated with a similar infection of the nose, sinuses and pharynx. Streptococcal allergies are of two types; the first is provoked by culture filtrates which produce an immediate skin reaction, and the second by dead bacteria. Tuberculosis allergies include phlyctenular keratoconjunctivitis, the infantile form of which is sharply differentiated from the adult form. In the former, basic tuberculous allergy almost always exists. In the adult form skin reactions to the tubercle bacilli are frequently negative. The condition is frequently recurrent and is associated with similar inflammatory lesions in the nasopharynx. Various toxic agents are a third factor in this complex reaction. In an illustrative case prompt recovery followed discontinuance of the use of barbiturates. (20 references.) Chas. A. Bahn.

Prado, Durval. Strange ocular complication caused from intoxication by sulfadiazine. *Arquivos Brasileiros de Oft.*, 1945, v. 8, Dec., pp. 169-172.

A medical undergraduate aged 24 years had a gonococcic urethral infection for which he ingested sulfadiazine

in a daily dosage varying from two to five grams for a total of three weeks, and without taking at the same time an alkalizing or other antitoxic drug. Five days later he developed a severe conjunctival irritation with slight photophobia and lacrimation. The next day he had a strong febrile reaction, and in the nasolabial fold there were a number of phlyctenules of the approximate size of the head of a match, with slight edema of the face. The second day after hospitalization the phlyctenular eruption spread over the whole body, and there was headache with weakness. The diagnosis wavered between smallpox and an allergic reaction. The subsequent treatment included nicotinic acid, vitamin C, and glyco-physiologic fluid by vein. Further symptoms included abundant thick and viscous salivation, nasal obstruction, occlusion of the eyelids with production of abundant conjunctival exudate, and an analogous condition of the nose. The bodily eruption broke down into small ulcers, which became covered with crusts, and these developed into irregularly pigmented spots of various sizes. Leukopenia and monocytosis supported the diagnosis of sulfamide intoxication. The twenty-second day of hospitalization the patient was discharged from the hospital still bearing the pigmented spots over the body. Two days later he began to lose the toenails and fingernails. These were subsequently regenerated, and the bodily spots lost their pigmentation. The corrected vision became normal, although photophobia and lacrimation continued for some time. There was symblepharon at both angles of each eye. (1 illustration.) W. H. Crisp.

Selfa, Enrique. Pseudomembranous conjunctivitis in whooping cough.

Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, March, pp. 200-205.

Acute conjunctivitis in whooping cough has two forms: (1) a toxic pseudomembranous form easily confused with diphtheritic conjunctivitis, and (2) a metastatic form which is not different from the usual acute conjunctivitis. Both types are benign and clear up without treatment in two to five days. Eight cases are reported; in one of the patients corneal ulcers developed, presumably as a result of overtreatment.

CORNEA AND SCLERA

Allen, J. H., and Erdman, G. L. Meningococcic keratoconjunctivitis. Amer. Jour. Ophth., 1946, v. 29, June, pp. 721-723. (See Section 5, Conjunctiva.)

Arruga, H. An instrument for keratoplasty. Arch. of Ophth., 1946, v. 35, March, pp. 299-300.

In passing sutures through a corneal transplant, there is always a certain amount of trauma. Arruga here describes an instrument devised to reduce the bruising to a minimum.

The sutures leave minute spots in the corneal graft, but in the great majority of cases these spots are invisible to the naked eye and do not impair the transparency of the corneal graft.

R. W. Danielson.

Arruga, H. Some modification in the fixation of the transplant in keratoplasty. Ophthalmologica, 1945, v. 109, April-May, pp. 269-270.

The author suggests a modification in the sutures by means of which the transplanted cornea is fixed directly to the cornea of the host. With very fine needles two sutures are placed, opposite to each other, and 1 mm. from the margin of the transplant. A suture is placed in the cornea of the patient before the diseased part is removed by a 4-mm. trephine. The graft is put into the defect with the sutures in the 12 and 6 o'clock positions. These sutures are also put through the margins of the wound in the cornea of the patient and knotted. The graft is pushed back with extreme care and the primary suture tied over the center of the transplant.

Alice R. Deutsch.

Falls, H. F., and Beall, J. G. Ocular varicella. Arch. of Ophth., 1945, v. 34, Nov.-Dec., pp. 411-412.

The ocular complications of varicella (chicken-pox) are rare. Usually these complications occur late in the course of the disease, the area involved is small and circumscribed, associated iridocyclitis is absent, and recovery is rapid and complete.

A physician, 30 years of age, developed ocular complications on approximately the seventh day of a severe attack of varicella. The conjunctiva of each eye revealed several small vesicular areas, each of which possessed a small areola of hyperemia. There was suggestive corneal anesthesia of the left eye. Both corneas showed a few scattered pinpoint areas which stained with fluorescein. In addition, the left cornea showed a definite zone of infiltration one-half to one millimeter in diameter and one to two millimeters from the limbus. This area was raised and stained diffusely with fluorescein. The cornea was thickened superficially, but no deep lesion could be seen. No

aqueous flare was noted. The zone of infiltration surrounding the phlyctenule receded rather promptly. The phlyctenule disappeared within a period of six to seven days, but slight corneal anesthesia persisted for at least ten days. Complete recovery occurred within a month after the onset of the ocular lesion. (Colored drawing.)

John C. Long.

Franceschetti, A., and Babel, J. A tentative anatomical classification of familial corneal degenerations. *Ophthalmologica*, 1945, v. 109, April-May, pp. 169-202.

This detailed study of the familial corneal degenerations is based on the histologic examinations of 14 corneas. The histologic findings are readily grouped to correspond to the clinically recognized types of dystrophy. In the first group, which consists of the lesions that are progressive and not congenital, there are two types that are dominant in hereditary pattern and one that is recessive. The two dominant forms—the granular and the lattice—are histologically characterized by a hyaline degeneration of the superficial lamellae of the corneal stroma and more particularly by the subepithelial deposition of a basophilic hyaline substance. The lattice form differs from the granular in that the degenerative changes in the stroma involve deeper strata and that the basophilic hyaline appears in larger masses. A third type, which is recessive and is called macular dystrophy, shows similar hyaline degeneration of the lamellae, and a granular albuminous substance is found in all the cells (stroma, epithelium, endothelium).

In the second group the dystrophies are congenital and stationary. One finds no hyaline degeneration, but instead, a

dissociation of the lamellae of the stroma and the deposition of a granular substance that may be a lipoid in the cells of the stroma. In the majority of cases the hereditary pattern is of the recessive type. Chemically and histologically the lesion is similar to that found in dysostosis multiplex (Gargoylism). (15 illustrations, 3 in color, bibliography.)

Alice R. Deutsch.

Giraudet, M. New instruments for keratoplasty. *Ophthalmologica*, 1945, v. 110, July-Aug., pp. 34-37.

The five new instruments which are presented in this paper were designed to help in the difficult procedures of keratoplasty. In using them it is not necessary to make any changes in the technique of the operation. (3 figures.)

Alice R. Deutsch.

Greene, P. B. *Keratoconus posticus circumscriptus*. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 432-433.

A sixth case of *keratoconus posticus circumscriptus* is described in one eye of a man who was 52 years of age. Just nasal to the center of the cornea the posterior surface of the cornea curved sharply forward so that the resultant thickness of the cornea at this point was about one-third that of the surrounding normal tissue. A nebula surrounded this area. In addition there was a small anterior subcapsular lens opacity and a somewhat larger opacity on the face of the fetal nucleus. All three of these opacities were in a direct line. It is possible that this condition represents a delayed separation of the lens from the cornea and is an aberration in development, although intrauterine inflammation may be considered a possible cause.

904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Henry Nathan Blum, New Orleans, Louisiana, died April 13, 1946, aged 69 years.

Dr. George Walter Caldwell, Los Angeles, California, died March 11, 1946, aged 79 years.

Dr. Hal Lovelace Foster, Kansas City, Missouri, died May 21, 1946, aged 87 years.

Dr. Charles Joseph V. Fries, Jr., Philadelphia, Pennsylvania, died May 7, 1946, aged 55 years.

Dr. Rufus Jackson, Baton Rouge, Louisiana, died February 21, 1946, aged 62 years.

Dr. Cassius D. Wescott, Chicago, Illinois, died May 6, 1946, aged 84 years.

MISCELLANEOUS

Operative surgical clinics in 17 Detroit hospitals will be featured the first morning of the eleventh assembly of the United States Chapter, International College of Surgeons, to be held in Detroit, October 21-22-23, 1946.

Special arrangements have been made to demonstrate the advances in gastric, thoracic, biliary, intestinal, genito-urinary, and plastic surgery. The various specialties, such as, ophthalmology, otolaryngology, and gynecology, the modern treatment of burns, fractures, and modern uses of wire in surgery will be featured.

For information concerning the Detroit Assembly or the primary qualifications for Fellowship in the United States Chapter, International College of Surgeons, write Dr. L. J. Garipey, secretary, 16401 Grank River Avenue, Detroit 27, Michigan.

At the annual meeting of the Better Vision Institute, June 28th, at the Park Lane Hotel, New York, new directors were elected. To represent the Manufacturer Group to June, 1948: Beverly Chew, C. O. Cozzens, J. E. Hansen, and Ben Ramaker. To represent the Supply House Group to June, 1948: Thomas Bryne, S. H. Edelstein, Roy Martin and C. N. Shelden. To represent the Optometric Group to June, 1948: Dr. John F. Hill, Dr. John Hughes, Dr. W. E. Malinka, and Dr. J. A. Palmer. To represent the Ophthalmic Dispensers' Group to June, 1948: W. A. Blocker, William Cook, J. A. T. Obrig, and A. F. Weber.

Directors whose terms carry over to 1947 are: In the Manufacturer Group: A. M. Krementz, Nathaniel Singer, M. H. Stanley, and E. H. Titmus; in the Supply House Group: W. B. Jones, Art Hager, H. E. McClenaghan, and Aaron Potter; in the Optometric Group:

Dr. Walter I. Brown, Dr. John J. O'Neil, Dr. F. A. Seward, and Dr. Jesse Wheeler; and in the Ophthalmic Dispensers' Group: H. B. Carpenter, Harry Chisholm, Oscar Cleal, and Henry Keller. Elected for one year to the Finance Committee were Beverly Chew, J. F. Taylor, Roy Martin, Aaron Potter, Dr. John F. Hill, and W. A. Blocker.

New industrial posters, to be released to industrial plants throughout the country for bulletin board use, will stress to workers: (1) the need for better vision in factory work; and (2) the need for protective goggles in hazardous occupations.

Under the title, The Treacher Collins Prize Essay, the Council of the Ophthalmological Society of the United Kingdom has instituted a prize of £100, awarded triennially, for the best essay submitted upon a subject to be selected by the Council. The prize shall be open to qualified medical practitioners of any nationality, and the essay shall be written in the English language.

The subject for the next award of the prize is: "Nutritional eye disease." The closing date for sending in essays for this award is December 31, 1947. Essays should be submitted to the Honorary Secretary, Ophthalmological Society of the United Kingdom, 5 Racquet Court, Fleet Street, E.C.4, from whom also any further particulars can be obtained. No name should be on any essay, but a distinguishing pseudonym or quotation, which should also be upon a sealed envelope containing the candidate's name and address. This envelope should accompany the essay.

SOCIETIES

The North Dakota Academy of Ophthalmology and Otolaryngology held its annual meeting at Bismarck, May 28th. Dr. H. L. Bair of Rochester, Minnesota, and Dr. M. T. Lampert of Minot, North Dakota, addressed the society on "Newer therapeutic measures in ophthalmology" and "Glaucoma, its mechanism."

The following officers were elected for the year 1946-47: E. D. Perrin of Bismarck, president; Dr. H. L. Reichert of Dickinson, vice-president; and Dr. M. T. Lampert of Minot, secretary.

An all-day meeting of the Reading Eye, Ear, Nose, and Throat Society was held at Reading Hospital, June 19th. Wet and dry clinics were held, followed by a paper by Dr. Francis Heed Adler and a paper by Dr. Harry P. Schenck.

At the annual meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology, held at the Merion Golf Club, Philadelphia, April 24-25, 1946, the following essays of ophthalmic interest were presented: "Some interesting phases of war ophthalmology," by James N. Greear, Jr., M.D.; "Anesthesia in Ophthalmology," by Walter S. Atkinson, M.D., and "Retinal arteriolar sclerosis," by Walter I. Lillie, M.D.

PERSONALS

On June 19th, at its eighty-eighth annual commencement, Northwestern University conferred the honorary degree of Doctor of Science upon Sir Stewart Duke-Elder. His citation read as follows:

"World-famed ophthalmologist, whose scientific researches have introduced significant conceptions of the nature and function of various ocular tissues; an ophthalmic surgeon of great skill and resourcefulness, who served his country during the war as Chief Consulting Ophthalmic Surgeon to the British Army; companion and advisor to ophthalmic medical offi-

cers of the United States Army stationed in Great Britain during the war; sole author of the world's most distinguished textbook on Ophthalmology."

Sir Stewart was presented by Dr. Derrick Vail, Professor and Chairman of the Department of Ophthalmology, Northwestern University.

Following the death of Dr. Mark J. Schoenberg, The National Society for the Prevention of Blindness announces the appointment of Dr. Willis S. Knighton as its chairman of the Committee on Glaucoma. With the guidance of the Committee, the direction of the demonstration glaucoma clinic, Manhattan Eye, Ear, and Throat Hospital of New York City has been assumed by Dr. Ferdinand L. P. Koch.

Dr. Rodolph M. Cutino, Brooklyn, has been appointed clinical professor of ophthalmology, and Dr. Mortimer A. Lasky has been promoted to clinical professor of ophthalmology at the Long Island College of Medicine, Brooklyn, New York.

TREATMENT OF GLAUCOMA WITH DI-ISOPROPYL
FLUOROPHOSPHATE (D.F.P.)*

PHILLIP ROBB McDONALD, M.D.

Philadelphia

Every ophthalmologist will agree that the treatment of glaucoma is frequently a difficult and harrowing problem. This is attested to by the numerous articles published every year dealing with the different aspects of this serious condition. The signs and symptoms of glaucoma are fairly uniform, but there can be no uniformity of treatment whether medical or surgical. Though numerous operative procedures have been devised for the relief of this ocular hypertension, it has only been within the past few years that drugs other than pilocarpine or eserine have been added to the physicians' therapeutic armamentarium.

Of the newer therapeutic agents, prostigmine acts like its chemical progenitor physostigmine or eserine in inhibiting the hydrolytic action of cholinesterase. Mecholyl, doryl, and furmethide are related chemically and act like acetylcholine in producing parasympathetic stimulation. The fact that none of these drugs is entirely successful in the relief of glaucoma is probably due to the fact that we are treating the patient by reason of objective findings, knowing little, if anything, of the etiologic basis for the disturbance. Previous studies^{1,2} have suggested that in patients with glaucoma there is some disturbance of the acetylcholine-cholinesterase balance.

Within the past few months a new

miotic has been introduced which gives great promise as a valuable adjunct in the treatment of glaucoma. This is di-isopropyl fluorophosphate (D.F.P.), one of a large group of fluorophosphates, and there is every reason to expect that other and probably more efficient miotics of a similar chemical structure may be introduced. Leopold and Comroe^{3,4} were the first to report on the effect of D.F.P. in the normal and glaucomatous eye. This drug is similar to eserine and prostigmine in inhibiting the cholinesterase. It is at least five-and-one-half times more potent and persistent than eserine. This may be due to the fact that its action is irreversible; that is, the cholinesterase is completely destroyed.

Leopold and Comroe have shown that, in the normal and glaucomatous eye, D.F.P. causes prolonged and marked miosis, ciliary spasm, false myopia, and a decrease in the intraocular pressure. This effect is not restricted to D.F.P., but has been reported as the property of other miotics.⁴ However, in the work referred to, D.F.P. miosis in the normal eye was found to persist for 14 to 27 days.

The studies herewith reported confirm the findings of these investigators³ in every detail. As recommended by them, the drug was used in a solution of peanut oil in concentrations of .05, .1, .2 percent. Peanut oil is used as the vehicle, for in an aqueous solution the potency of the drug is lost in about seven days.

*From Wills Hospital.

The present investigation was carried out to determine the advantages and disadvantages of using this drug routinely on clinic patients. In order to prove or disprove the efficacy of this drug over other miotics only those patients (with two exceptions) whose glaucoma was uncontrolled by the use of pilocarpine and/or eserine were accepted for trial. Cases in which the tension consistently ran greater than 30 mm. Hg (Schiotz) were considered as uncontrolled. The greatest percentage of cases fell in the group classified as chronic simple glaucoma. Some of the patients had fairly high tensions (60 to 70 mm. Hg), but no cases of primary acute congestive glaucoma are included in this series. The few cases that were seen responded to the usual miotic therapy.

PROCEDURE

The patients were all examined by me and the only cases rejected for therapy were those with blind painful eyes whose misery the drug might increase, or those who because of infirmities or geographic location could not return for observation every three to six days. The routine procedure was to have the patient's vision and tension checked. One drop of 0.1-percent D.F.P. was then instilled in the glaucomatous eye or eyes. After 45 minutes had elapsed, the tension was rechecked. In practically every instance, within this period of time, the tension was considerably lower. In a few cases there was some pericorneal injection; in patients whose iris was intact the miosis was usually pronounced. The patients were told to discontinue all previous medication and were given .1-percent D.F.P. to use either twice or three times a day, depending on their primary response. They were advised to expect some brow or eye ache and told that it might be severe. Aspirin was recommended for the relief of the discomfort.

With few exceptions all patients were examined again in 48 and 72 hours. On re-examination a number of patients stated that they had not used the drug or that they had used it only once since the initial drop.

In practically every instance the tension was lower than it had been initially, and, except for 10 patients who steadfastly refused therapy, all were willing to continue. The seriousness of their condition was explained to them, and it was pointed out that this was the first time in quite an interval that their tension had been controlled. At the second visit, if the tension had been satisfactorily reduced, the patients were instructed to use one drop of D.F.P. either once a day or every other day—if the tension was on the borderline, they were requested to use the drug three times a day. If the patients were insistent that the medicine was too strong, they were given .05-percent D.F.P. Those that complained of loss of vision were shown by means of a -1.00 or $-1.50D.$ sphere held in front of their lens that the decrease in visual acuity was brought about by a change in the refractive error.

At the time of the 72-hour visit one could obtain a fairly good estimate as to whether the patient's condition was controlled or not. At this time the frequency of the medication was again increased or decreased. Those who were still in an uncontrolled state were either given .2-percent D.F.P. to try for another 48 hours, returned to their old miotic, or admitted to the hospital for surgical intervention. Most of the patients were seen at weekly intervals for the first month and then every two to three weeks for the duration of this study. After the first week, most of the discomfort had abated, the blurring of vision was less noticeable, and the patients were, on the whole, content to continue the new therapy. Many

of them were quite pleased to be able to get along on one or less drops a day. This group was instructed to use the medicine at night so that the blurring of vision would be less disturbing.

RESULTS

The results of this study are summarized in table 1. The patients have been divided into two groups, controlled and not controlled. The data on white and colored patients have been separated to determine if there was any difference in the effect of the drug, since it is well known that persons of the colored race are more resistant to therapy. It will be noted that 82 patients have been seen and 122 eyes have been treated. Five of the patients, three white and two colored, had one eye controlled and the other not. The criteria for control was a tension consistently below 30 mm. Hg (Schiotz)—two tonometric readings of 30 mm. or above during the four months' period placed the patient in the category of having uncontrolled glaucoma.

Several interesting features are presented by these data. It is noteworthy that 57.4 percent of the patients' glaucomatous condition was considered as uncontrolled. Since it had been controlled in none of them by means of miotic or miotics previously used, the results speak well for the drug. Of the eyes that were controlled, 30 percent had a vision of less than 1/60; of the uncontrolled group, however, 50 percent had vision of 1/60 or less. This is not surprising, for in any clinic the patients with absolute or advanced glaucoma represent a fair proportion of the group that is uncontrolled.

In evaluating any therapy one cannot consider the effect of the drug alone, but must also consider the patient's tolerance of it. For this reason the 10 patients who refused therapy were considered as being uncontrolled. This group represents a

total of 14 eyes, half of which had a vision of 1/60 or less, and the other half 6/60 or better. In five of the seven eyes with vision 6/60 or better, the tension was satisfactorily reduced following the initial therapy; the tension was still reduced at the end of 48 hours despite the fact that only one or no drops had been used at home. The patients, however, were adamant in refusing further therapy. Those with blind eyes were encouraged but not coaxed to continue D.F.P. Neither approach was of any avail.

FREQUENCY AND STRENGTH OF MEDICATION

The distinct advantages of this drug are its relative potency and prolonged ac-

Fig. 1 (McDonald). Colored man, aged 59 years. Glaucoma first diagnosed June 15, 1945. Visual fields show peripheral contraction with nasal step O.S. Prior to D.F.P. therapy, V.O.D. 6/9 + 1; V.O.S. 6/12 + 1 without correction. Vision after four months' therapy, O.D. 6/9 + 2; O.S. 6/6 without correction. No significant change in visual field.

tion. Leopold and Comroe have pointed out that miosis in glaucomatous eyes is much more prolonged than that produced by any other miotic and that it is even more prolonged in the normal eye. Of the group who were controlled, approxi-

mately 63 percent required only one to seven drops of 0.1-percent D.F.P. a week. The prolonged effect of this drug can be

Fig. 2 (McDonald). White man, aged 74 years. Glaucoma first diagnosed May 23, 1944. Elliot trephining O.S. April 13, 1945. Visual fields show peripheral contraction with nasal step. seen in figure 1. This colored patient received one drop of 0.1-percent D.F.P. in his left eye in the clinic on March 8, 1946, but because of the discomfort it brought on he did not use the medication at home. Twenty-three days elapsed before the tension rose to its previous level. He was subsequently placed on 0.05-percent D.F.P. and now tolerates 0.1 percent without difficulty. One drop a week now maintains his tension at a satisfactory level.

This is not always the case, as can be seen in figures 2 and 3. After one week of therapy (fig. 2) this patient was returned to his previous miotic, and within four days his tension had risen to 31 mm. Hg (Schiotz). He is now satisfactorily controlled with one drop of 0.1-percent D.F.P., daily. The individual whose tension curve is shown in figure 3 did not use the medication after the ini-

tial drop in the clinic. When she returned, 96 hours later, the tension had risen but was still lower than it had been for several months. She is now well controlled on one drop a day.

The group who were uncontrolled were naturally all requested to use their drops more frequently. In a few instances, the drug was given more than three times a day; but it was found that, if a patient was not controlled on three drops a day, increasing the frequency was of no avail. This is to be expected because of the prolonged action of the drug.

The most satisfactory strength of D.F.P. to use routinely was found to be 0.1 percent; it was used initially in all cases. The strength was reduced to 0.05 percent if the patients complained too bitterly or increased to 0.2 percent if the tension was not satisfactorily controlled.

Fig. 3 (McDonald). White woman, aged 69 years. Glaucoma first diagnosed July 17, 1939. Visual field O.S. shows large Bjerrum scotoma. Uncorrected vision O.S., prior to and following therapy, 6/6. No change in visual field.

It was found that reducing the strength of the drug was no more effective than reducing the frequency plus some persuasive argument. Likewise, if a patient was not controlled with 0.1-percent D.F.P., he

was not likely to be controlled with a stronger solution. Of the group of patients now controlled, only one is using 0.2-percent D.F.P. The majority of those that are uncontrolled have been tried with 0.2-percent D.F.P. at some time or other.

FALL IN TENSION

The efficacy of any miotic is determined by its ability to reduce the ocular tension. This reduction in tension must be maintained within the accepted limits

of a week or so, the tension would gradually rise—in the controlled cases to a level in the low twenties; and in the uncontrolled cases, although not under 30 mm. Hg, in most instances to a level considerably lower than before. Figures 4 and 5 show the characteristic reduction in tension that has been maintained in the group that has been controlled. Figure 6 shows the precipitous drop in tension in response to both mecholyl and prostigmine and to D.F.P., yet, despite

if the patient is to continue on medical treatment. In an attempt to determine whether the immediate effect of D.F.P. was of any value in prognosticating whether the intraocular pressure could or could not be controlled with this therapy the immediate drop and 48-hour fall in tension has been summarized in table 1. Perusal of these figures shows that there are no significant differences for the two races in either the controlled or uncontrolled groups. It is obvious that for all groups the tension was lower after 48 hours of therapy. As is the case with other miotics, the initial drop was frequently precipitous and then, over a pe-

riod of a week or so, the tension would gradually rise—in the controlled cases to a level in the low twenties; and in the uncontrolled cases, although not under 30 mm. Hg, in most instances to a level considerably lower than before.

RISE IN TENSION

Eserine and prostigmine are known occasionally to cause a rise in tension in the normal and the glaucomatous eye. This may be caused by the vasodilatory effect of these drugs. Since D.F.P. is a much more powerful inhibitor of the cholinesterase, it might be expected that this would be noted more frequently. In the control group, seven eyes showed an initial rise in tension of 3 to 7 mm. Hg (Schiotz); all of this group, however, showed a satisfactory drop in tension at the end of 48

hours. In the uncontrolled group, 10 patients showed an initial rise of from 2 to 35 mm. Hg (Schiotz), and only one of this group showed an appreciable drop below his initial tension within 48 hours.

Fig. 4 (McDonald). Colored woman, aged 65 years. O.S. enucleated following glaucoma surgery in 1934. Glaucoma first diagnosed in O.D. February 14, 1934. Visual field shows small central island. Prior to therapy uncorrected and corrected V.O.D. 6/30+1. After four months of D.F.P. therapy corrected and uncorrected vision, 6/15. No change in visual field.

The significance of this will be discussed later.

APHAKIC GLAUCOMA

Of the entire group, the 15 patients with aphakic glaucoma were the most satisfactory to treat. This was so for several reasons. First, they seldom complained of discomfort. Leopold and Comroe² have pointed out that the probable reason for this is that the zonule is not intact, and they have also ingeniously surmised that the absence of pain supports the Tscherning theory that the fibers are stretched from ciliary spasm. Secondly, since accommodation is absent, these patients do not complain of blurring of vision. Lastly, the results have been uniformly successful in the uncomplicated cases. The tension record shown in figure 7 is characteristic of this group. This

patient developed glaucoma following an intracapsular cataract extraction and was admitted to the hospital for a cyclodialysis. When placed on D.F.P. the tension was immediately reduced. A cyclodialysis was performed when the tension was lowered. Following operation the tension rose to its original pre-D.F.P. level, and the drug was tried again with a satisfactory response. In order to insure that this reduction was not a delayed response to the operation, all medication was stopped for one week whereupon the tension rose again. It is now satisfactorily controlled by the use of one drop of 0.1-percent D.F.P. every other day.

As to the three failures, one patient had had a traumatic cataract removed eight years previously, the eye was blind, and there was a marked bullous keratitis. Another patient had had a cyclodialysis; when seen, the chamber was partially

Fig. 5 (McDonald). White man, aged 53 years. Glaucoma first diagnosed in 1935. Ellipt trephining O.S. April 25, 1938. Visual field shows large Bjerrum scotoma O.D. Prior to therapy, corrected V.O.D. 6/21; V.O.S. nil. After D.F.P. therapy corrected V.O.D. 6/15-1. No change in visual field.

filled with blood and exudate. The third patient had had a secondary glaucoma with a dislocated lens; when seen, both pillars of the iris were incarcerated and the wound was bulging.

CAUSES OF FAILURE

All the cases have been reviewed critically to determine if there is any common denominator by means of which one could predict success or failure of the drug. As is frequently and unfortunately the case in a large series of clinic patients, the records are not complete enough to evaluate each case thoroughly—post-operative notes are incomplete, visual fields are not reliable, and there are

other omissions. Unfortunately, facilities for the gonioscopic examination of all these patients were not available. Visual fields, although taken, were sometimes missing, and differences in their record-

Fig. 6 (McDonald). White woman, aged 65 years. Glaucoma first diagnosed January 26, 1946. Basal iridectomy O.S., January 30, 1945. Visual field O.D. small central island. V.O.D. 1/60; V.O.S. nil. Basal iridectomy O.D., March 29, 1946. Patient has not been seen since discharge from hospital.

ing did not permit satisfactory comparisons.

As shown in table 1, 10 patients refused therapy because of the discomfort—a real objection to the use of D.F.P. This obstacle, however, could be partially overcome by having the patient hospitalized for the first few days of therapy, when adequate relief for the discomfort could be provided.

Of the uncontrolled group, eight patients with useful vision were admitted to the hospital and subsequently operated upon. Prior to operation, most of them had had every known type of therapy: mecholyl and prostigmine, furmethide, doryl, and D.F.P. None of these drugs satisfactorily lowered the tension. Of this group the condition of only two has

been satisfactorily controlled by operation; in the others, despite one to three operations on each eye, the tension is still uncontrolled. Two of these patients and one other not yet operated upon, I

Fig. 8 (McDonald). White woman, aged 60 years. Glaucoma first diagnosed January 30, 1946. Corrected V.O.D. 6/9; V.O.S., light projection. Visual fields show small central island O.U. Patient has not been seen since discharge from hospital.

believe, have been made worse by the use of D.F.P. The patient whose tension curve of the right eye is shown in figure 8 had glaucoma in both eyes. She was admitted for surgery of the uncontrolled left eye. D.F.P. was ordered for both eyes to determine what effect it might have on the tension. Despite adequate miosis, the tension in both eyes started to climb and was relieved only by operation. The patient whose tension curve of the right eye is shown in figure 9 had an essential atrophy of the iris of the right eye. This eye was seemingly controlled with the old miotic; but the left eye, which had undergone a basal iridectomy, was not. The patient was placed on D.F.P. for the left eye and responded to the therapy. To simplify treatment, D.F.P.

was ordered for the right eye also. At no time has there been any miosis in this eye, and despite discontinuance of D.F.P. and a return to his old as well as other miotics, his tension in the right eye is still considerably higher than was recorded prior to therapy. The two other cases of atrophy of the iris in this series have also failed to respond to D.F.P. One case of glaucoma secondary to thrombosis of the central retinal vein was unaffected by the drug.

DISCUSSION

Considering the fact that, with two exceptions, only cases which were uncontrolled with the usual miotics are included

Fig. 9 (McDonald). White man, aged 58 years. Glaucoma first diagnosed September 11, 1944. Basal iridectomy O.S., September 19, 1944. Uncorrected V.O.D. 6/12; O.S. 6/9-1. Visual fields show small central island O.U. Visual acuity has not changed since therapy was initiated. Awaiting operation.

in this series the successful control of 57.4 percent of this group shows that D.F.P. is a valuable adjunct in the medical treatment of glaucoma. Glaucoma patients as a group tend to be somewhat

apprehensive; many of them follow their tensions as religiously as some patients with arterial hypertension. These patients are most grateful for the interest shown in them and for the fact that some form of therapy is now available to control their tension. This is especially so in those who by some misfortune have lost the vision in one eye following one or more surgical procedures.

It is not my purpose to discuss the pros and cons of the medical versus the surgical treatment of glaucoma. I personally subscribe to the school of thought advocating early operation. However, every ophthalmologist has one or more patients for whom, for some reason or other, he would gladly defer surgery if the tension could be satisfactorily controlled by medical means.

This study, I believe, has shown that D.F.P. can be used with impunity on clinic patients, provided the physician prescribing the drug is aware of its advantages and disadvantages. The initial drop in tension is most gratifying, this is frequently precipitous. It is probably due to the fact that the glaucomatous eye is sensitive to acetylcholine.⁴ Since D.F.P. inhibits the cholinesterase, the acetylcholine in the eye is allowed to become effective. After the tension has been reduced, the sensitivity to acetylcholine is gradually lost. This probably explains the gradual rise in tension after the first 48 hours of therapy, when the more stable effect of D.F.P. is apparent.

In my opinion it is unwise to keep the tension too low in an eye that has been maintaining an elevated tension. If the tension was below 20 mm. Hg (Schiotz) when the patients were seen for the second time, they were instructed to reduce the frequency of the instillation of the drops. If the patient's glaucoma is amenable to one to two weeks of therapy one can usually determine whether the drops

are required once or twice a day or once or twice a week.

Leopold and Comroe² have pointed out that the effect of D.F.P. is much shorter in the glaucomatous eye than in the normal eye. They attribute this to some fundamental disturbance in the acetylcholine-cholinesterase balance in the eye. A few of the cases in this series which have been reported as uncontrolled with D.F.P. have subsequently been controlled when a drop of 20-percent mecholyl was instilled in conjunction with the D.F.P.

Although three strengths of D.F.P. were initially used in this study, I believe that the most satisfactory strength is 0.1 percent. This may, on occasion, have to be reduced for the susceptible patient. Increasing the strength of the solution is seldom of benefit. Of the 42 patients who were controlled, only one is using 0.2-percent D.F.P. The stronger solution has been tried without success in the therapy of many in the uncontrolled group.

As is the case when other miotics are used, there can be marked miosis and still no significant decrease in tension. In attempting to evaluate the reasons for success or failure of this drug the degree of miosis was usually noted. In eyes with an intact iris, except in a few of the cases with iris atrophy, the miosis was usually extreme. The degree of miosis was of no prognostic value as to whether the drug would be successful or not. Eyes that had undergone complete iridectomy often responded to D.F.P. therapy without showing any significant miosis.

This drug seems to be equally effective in reducing the tension in the white and in the colored race. From the data available the frequency of medication required to control the glaucoma was the same in both groups.

The limited experience gained by the

use of D.F.P. in this series of patients has uncovered several facts which would appear to be of value in guiding those who may be using it for the first time. This drug is not a cure-all for glaucoma. It may initially cause a fall in tension; then, after a period of several weeks, the tension may gradually rise, and the glaucoma can no longer be considered as controlled. The drug may have little or no effect on the tension. These are characteristics common to all miotics. In cases of absolute glaucoma, the percentage of successes is much lower than that of the failures; this is to be expected, however, and the drug should not be condemned because it is not effective in such cases.

If the tension does not fall or if it rises 60 minutes after the initial drop, the patient should be carefully watched. If, after a 48-hour interval, the tension has not shown an appreciable fall, some other type of therapy should be instituted, provided one is satisfied that the patient is using the miotic frequently enough and that a supplemental miotic is not indicated. It must also be realized that in certain cases D.F.P. may hasten rather than retard the need for surgical intervention. The arteriolar vasodilation and/or ciliary spasm caused by the drug may swing the pendulum in the wrong direction.

The advantages of the drug, however, are believed sufficient to warrant further clinical studies. D.F.P. is by far the most potent and persistent of the newer miotics. In this series of patients there have been no symptoms of systemic reaction or of local irritation.

It is to be hoped that this new drug will be given additional clinical trial. Many ophthalmologists receive every new miotic with great enthusiasm and try it out on those of their patients who have been uncontrolled with every known form of medical and surgical therapy. When the drug does not work it is soon dis-

regarded and frequently condemned. The treatment of glaucoma cannot be standardized, and the patient's reaction to various therapeutic procedures must be carefully evaluated. It is fairly well established now that there is some disturbance of the acetylcholine-cholinesterase balance in glaucoma. It may be that some patients require a drug which inhibits the cholinesterase as well as one that supplies acetylcholine or its counterpart. One should then be prepared to treat the patients on a sound pharmacologic basis rather than empirically.

SUMMARY

1. In a series of 82 patients representing 122 glaucomatous eyes that were uncontrolled by previous miotic therapy, D.F.P. successfully controlled 57.4 percent of the eyes.

2. D.F.P. has been shown to have the following advantages: (a) It is more powerful than any other known miotic; (b) its action is prolonged, many patients requiring seven or less drops a week to keep the tension controlled; (c) it does not cause a local irritative reaction; (d) it would appear to be especially effective in aphakic glaucoma.

3. The disadvantages in using D.F.P. are: (a) The marked discomfort it may produce during the first few days of therapy; (b) the blurring of vision caused by ciliary spasm; (c) the occasional rise in tension that is believed to result from the arteriolar dilatation and effect on the ciliary body caused by the drug.

4. One cannot prognosticate which cases will respond to therapy and which will not. If the tension has not dropped within 48 hours recourse should be had to other measures.

5. D.F.P. must be used judiciously, and correct dosage determined for every patient.

The author is indebted to Drs. Leopold and Comroe of the University of Pennsylvania for supplying the D.F.P. used in this study and to the Attending Sur-

geons of the Wills Hospital for the clinical material.

INDICATIONS AND CONTRAINDICATIONS FOR KERATOPLASTY AND KERATECTOMIES*

RAMÓN CASTROVIEJO, M.D.

New York

The surgical procedures used for the treatment of corneal opacities are keratoplasty and keratectomies. Whenever possible, keratoplasty is to be preferred, because the visual acuity obtained with this type of operation is considerably better than that which can be obtained with keratectomies.

With keratoplasty, when the transplant remains completely transparent it is not rare to obtain vision of 20/20 or better, whereas with keratectomies there is always a certain amount of irregular astigmatism and varying degrees of haziness with which vision is rarely improved to beyond 20/100. This presentation is based upon the study of more than 600 keratoplasties and over 100 keratectomies performed at the Institute of Ophthalmology, Columbia Presbyterian Medical Center.

Inflammation contraindicates kerato-

plasty and keratectomies. Whether the inflammation is due to disease (infection, specific lesions, or conditions caused by viruses) or follows trauma, the operation should be postponed until all signs of inflammation have subsided and the eye has remained quiet for at least six months.

In cases of burns caused by chemicals, flame, and molten metals, it is advisable to wait about a year until cicatrization has been completed and photophobia, blepharospasm, and lacrimation have disappeared. Then, when the eye is quiet, the sequela of the injury may be treated either by keratoplasty or keratectomies.

Glaucoma contraindicates these operations. In glaucomatous eyes with corneal opacities, where improvement of vision may be expected by keratoplasty or keratectomies, the glaucomatous state has to be treated first by appropriate operations. When an operation for the control of glaucoma is performed as a preliminary to a keratoplasty, it is advisable to make a very large iridectomy. This procedure will leave the eye in a more favorable condition for the keratoplasty with less danger of

*From the Institute of Ophthalmology, Columbia Presbyterian Medical Center. Read at the eighty-first annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, November, 1945.

anterior synechia and recurrence of glaucoma. These complications often lead to nebulosity or opacification of the graft.

In regard to prognosis after keratoplasty and keratectomies, patients may be divided into three main groups:

1. These are very favorable cases for keratoplasty in which a high percentage of clear grafts and considerable improve-

thus defeating the purpose of the operation (fig. 2).

(c) Interstitial keratitis, when the opacity is not too dense and extensive and the transplant will remain in contact with fairly healthy corneal tissue. To prevent a recurrence of the interstitial keratitis and subsequent nebulosity or opacification of the graft, the infection responsible for the

Fig. 1 (Castroviejo). Eyes with central corneal opacities before (A) and after (B) keratoplasty.

ment of vision may be expected, with final vision averaging better than 20/50 and not infrequently 20/20 or better. They occur in the following ocular involvements:

(a) Central corneal opacities where the transplant will remain surrounded by healthy corneal tissue (fig. 1).

(b) Keratoconus, when vision cannot be improved by regular or contact lenses or when the contact lenses are not tolerated. In these cases the transplant has to be large enough to include the conus, otherwise the transplant has a tendency to heal unevenly around the edges and in some instances may protrude, causing pronounced astigmatism or myopia and

keratitis must be cleared or at least treatment of the infection well advanced before the keratoplasty is performed (fig. 3).

2. These cases are less favorable for keratoplasty but still likely to give a high percentage of transparent grafts and considerable improvement of vision. They comprise such involvements as:

(a) Corneal dystrophies (the Fleischer, Haab-Dimmer, Groenow, and Salzmann types) (fig. 4).

(b) Superficial opacities which extend over the whole area of the cornea but in which the epithelium has a healthy appearance, there is not superficial vascularization, and it can be seen either by

Fig. 2 (Castroviejo). Keratoconus before (A) and after (B and C) keratoplasty.

observation with the naked eye, oblique illumination, or examination with the slit-lamp that most of the stroma and the inner layers of the cornea are normal (fig. 5).

(c) Tear-gas burns, when there is no pannus-type superficial vascularization;

Fig. 3 (Castroviejo). The result of keratoplasty in a case of interstitial keratitis.

Fig. 4 (Castroviejo). Corneal dystrophy before (A) and after (B) keratoplasty.

the destruction of the cornea includes only a limited area of the superficial layers, and enough healthy cornea remains underneath to nourish the graft (fig. 6).

Fig. 5 (Castroviejo). Extensive superficial corneal opacity before (A) and after (B) keratoplasty.

Fig. 6 (Castroviejo). Tear-gas burns of cornea before (A) and after (B) keratoplasty.

(d) Adherent leukomas. Keratoplasty should be preceded by an iridectomy to free the iris from the corneal scar.

(e) Descemetocelles (following corneal ulcers or surgical procedure) in or near the pupillary area, when the whole opacity

including the descemetocelle may be substituted by a corneal graft (fig. 7).

(f) Interstitial keratitis with more extensive and denser opacity than that already mentioned in (c) under group 1, but still with sufficient permeability in the corneal stroma, giving reason to suppose

Fig. 7 (Castroviejo). Corneal opacity with descemetocelle before (A) and after (B) keratoplasty.

Fig. 8 (Castroviejo). Extensive and dense interstitial keratitis before (A) and after (B) keratoplasty.

that the transplant will remain more transparent than the original opacity (fig. 8).

3. These cases are unfavorable for keratoplasty. They occur in such involvements as:

(a) Corneal scars which, including the pupillary area, extend to the limbus. In

Fig. 9 (Castroviejo). Nebulous transplant in an example of corneal scar extending to the limbus.

these cases the transplant is likely to become vascularized and subsequently nebulous or opaque. In these cases keratoplasty may be performed with guarded prognosis. It should be preceded by a preliminary large iridectomy correspond-

Fig. 10 (Castroviejo). Extensive corneal leukoma before (A) and after (B) partial superficial keratectomy.

ing to the corneal opacity. If the transplant should become nebulous the eye is generally left in a more favorable condition to undergo a second keratoplasty in the pupillary area because the cornea is usually left with a haziness which is not as dense as the original leukoma (fig. 9).

Fig. 11 (Castroviejo). Dystrophia adiposa. Before keratoplasty (A). One month after keratoplasty (B). (This graft became opaque several weeks later.) Stages in opacification of the graft after keratoplasty (C and D).

(b) Extensive leukomas in which the transplant will be surrounded in more than one half of its circumference by dense scar tissue. In these cases a partial superficial keratectomy which removes as much as possible of the thickness of the scar may improve vision. If, after kera-

Fig. 12 (Castroviejo). Corneal opacity after dynamite explosion. Before operation (A). After preliminary partial superficial keratectomy (B). After subsequent keratoplasty (C).

tectomy, vision has not improved as much as desired, the eye is left in a more favorable condition to undergo a keratoplasty (fig. 10).

(c) Band-shaped opacity. In these cases the transplant generally becomes invaded by the opacity, and one should preferably perform a partial superficial kera-

tectomy, excising the affected area of the cornea.

(d) Dystrophia adiposa. The transplant is invariably invaded by the dystrophy and becomes opaque (fig. 11). In these cases it is preferable to perform a partial superficial keratectomy as extensive as may be necessary to excise the whole affected area, in surface and in depth preserving as much as possible of

Fig. 13 (Castroviejo). Opaque transplants after keratoplasty in two examples of dense vascularized leukomas of the cornea.

the normal peripheral corneal epithelium, which will serve to epithelize the dissected corneal area.

(e) Deep corneal burns due to tear gas, whether the eye is quiet or suffers from photophobia, blepharospasm, and lacrimation. In these cases it is advisable to carry out a partial superficial keratectomy, with the removal of all of the superficial affected area and to the depth necessary to reach clear corneal tissue without perforation. By means of this procedure enough vision may be obtained to make further surgery unnecessary, but if the improvement of vision obtained is not

sufficient, the eye is generally left without photophobia, blepharospasm, and lacrimation and remains in a more favorable condition to undergo a keratoplasty.

(f) Extensive corneal opacities caused by explosions which leave the cornea with a tattooed appearance. A partial superficial keratectomy is likely to improve vision sufficiently; if not, a keratoplasty may be performed afterward with better chance of success (fig. 12).

(g) Corneal opacities in aphakic eyes, particularly after intracapsular cataract extraction. These cases are unfavorable because the iris, capsule of the lens, or vitreous is likely to become incarcerated in the corneal incision. This complication is very likely to render the transplant quite nebulous or opaque.

(h) Extensive corneal opacities, with superficial vascularization of the pannus type, generally caused by burns (chemical, flame, or molten metals), do not lend themselves well to keratoplasty, and the transplant invariably becomes opaque (fig. 13). These cases are better treated by means of superficial keratectomies. If

Fig. 14 (Castroviejo). Dense vascularized leukoma before (A) and after (B) total superficial keratectomy.

the opacity does not extend over the whole area of the cornea, the healthy cornea should be preserved, and only the superficial layers of the cornea be dissected, including the opacity with the blood vessels. The operation must be followed by X-ray treatments to prevent the

Fig. 15 (Castroviejo). Dense vascularized leukoma and symblepharon before (A) and after (B) total superficial keratectomy with corneo-conjunctival plastic operation.

recurrence of corneal vascularization. If the opacity extends over the whole corneal area, a total superficial keratectomy should be performed followed by irradiation to prevent the recurrence of corneal

Fig. 16 (Castroviejo). Example of cases suited to corneal surgery. Pemphigus (A). Corneal opacity with calcareous degeneration in a glaucomatous eye (B).

vascularization (fig. 14). If, in addition to an opacity of the cornea, there is a symblepharon, a total superficial keratectomy for visual purposes must be combined with corneo-conjunctival plastic (fig. 15), or corneo-conjunctival plastic and buccal-mucosa implant for the correction of the symblepharon.

Fuchs's epithelial dystrophy, extensive corneal opacities with calcareous degeneration, corneal opacities caused by pemphigus, and corneal opacities with extensive anterior synechiae are not improved by keratoplasty or keratectomies (fig. 16).

Eyes with corneal opacities of many years' standing, particularly when there is a pronounced nystagmus, are not suitable for keratoplasty for visual purposes

because these eyes have a high degree of amblyopia. Although the transplant may remain transparent, vision does not improve (fig. 17).

Keratoplasty is contraindicated even in the presence of a favorable eye in patients who during the examination are very uncoöperative, the so-called high-strung type. In these it is reasonable to as-

Fig. 17 (Castroviejo). Clear corneal transplant in a case of corneal scar with pronounced nystagmus.

sume that, on account of poor coöperation, the postoperative recovery will be stormy, with great danger of severe complications such as extensive anterior synechiae and subsequent secondary glaucoma or prolapse of the transplant leading to loss of the eye.

COMMENT

Keratoplasty and keratectomies are no longer surgical procedures of uncertain results. Sufficient numbers of cases have already been studied to determine fairly accurately in which cases this type of surgery will be helpful. Further study of patients operated upon by keratoplasty or keratectomies will give additional data in regard to the feasibility of employing these techniques in a greater variety of corneal affections, particularly with reference to those which at present are considered unfavorable cases.

635 West 165th Street (32).

DISCUSSION

DR. WILLIAM H. CRISP (Denver): I should be obliged if Dr. Castroviejo would tell us something about the very extreme cases of keratoconus, rarely seen, in which there is great bulging of the cornea and some cloudiness of the apex of the extreme cone.

I should also be obliged if Dr. Castroviejo would tell us a little more as to whether one may expect any gain from X-ray treatment of general vascularity from a tear-gas burn many years after the accident occurred.

DR. F. H. VERHOEFF (Boston): I wish to ask Dr. Castroviejo his opinion as to the possibility of recurrence of corneal dystrophy in a graft, and whether in this respect there is any difference in the various types of dystrophy. I know such recurrence has been recorded and I should like to know whether he thinks its likelihood is great enough to contraindicate keratoplasty.

DR. RAMÓN CASTROVIEJO (closing): Dr. Crisp has asked if a very extensive keratoconus is suitable for keratoplasty. If the keratoconus is very extensive but one feels that the whole conus can be replaced by a transplant $6\frac{1}{2}$ or 7 mm. in size, the eye is suitable for keratoplasty. If the conus is so large that in order to replace the whole conus, a transplant larger than 7 mm. will be required, the operation is likely to be followed by severe complications such as extensive synechiae leading to secondary glaucoma. In such a case it is advisable to flatten the conus by treating approximately 6 mm. of the center of the conus with a fulgurating current applied with a fine electrolysis needle. After the treatment, the eye has to be bandaged with a pressure dressing and the pressure dressing

continued until cicatrization has been completed. This treatment causes corneal opacity of the treated area but the eye is rendered more favorable for keratoplasty when the corneal curvature has been brought within approximately normal limits.

In regard to extensive vascularization of the cornea treated by irradiation, my experience has shown that once the blood vessels have already formed, treatment by X-ray or radium is of no value. Irradiation has to be given before the blood vessels have formed. After keratectomies, X-ray treatment is instituted on the same day or on the day following the operation, when the capillaries are beginning to form and are easily obliterated by irradiation. In this way, vascularization of the cornea is prevented.

To Dr. Verhoeff's remark of the likelihood of the transplant's becoming involved by the cornea of the host affected with a dystrophy, it can be said that in some instances, the dystrophy of the host invariably invades the transplant; for example, in cases of Fuchs's dystrophy and dystrophia adiposa. In other dystrophies, the transplant is likely to remain transparent. Because of the uncertainty in regard to the final transparency of the transplant in cases of dystrophies, these have not been classified in the most favorable group but in the less favorable. However, the transplant is likely to remain more transparent or at least clearer than was the original opacity.

DR. VERHOEFF: But they undergo a recurrence of the same type of opacity?

DR. CASTROVIEJO: Yes, in some cases the transplant is partially or totally involved by the same dystrophy of the host.

ARSENICAL EYE BURNS*

A CASE REPORT

GEORGE I. UHDE, M.D.†

Portland, Oregon

Lewisite is an arsenical compound, developed toward the end of World War I but never actually used in combat. The lesions are much more painful than those caused by mustard gas. Immediately on exposure to lewisite, there is severe eye pain, blepharospasm, and lacrimation resulting in instant warning to any potential victim. For that reason, there did not occur so many nor so severe burns as on exposure to mustard gas.

PHYSIOLOGIC EFFECTS ON EXPOSURE TO THE VAPOR

The vapor of the pure substance is not lacrimatory but is very irritant to the upper respiratory tract, thus causing a reflex flow of tears. Lewisite vapor, surprisingly enough, does not cause corneal damage, at least in some animals, until large concentrations are reached. Eight patients out of 1,097, or 0.7 percent of the eye, ear, nose, and throat patients, were treated for lewisite-vapor burns at Edgewood Arsenal during the 17 months preceding March 1, 1943. These burns were all very mild.

PHYSIOLOGIC EFFECTS OF A SPLASH BURN

The site of contamination of a rabbit's cornea with a lewisite droplet becomes im-

mediately opaque. The lewisite appears to soak into the cornea almost instantaneously. There is obvious severe pain; the animals frequently squeal. Lid spasm is very severe for 15 to 30 seconds. The pupil may constrict in about two minutes. The corneal epithelium, which is so hazy that it is difficult to make out the iris, begins to loosen in about one to two hours.

Fig. 1 (Uhde). Rabbit's eye showing severe chemosis one hour after contamination with 0.0002 c.c. of lewisite.

The denuded corneal surface stains with fluorescein. The conjunctiva is severely edematous and contains numerous small hemorrhages (fig. 1). Edema extends into the substantia propria. The whole thickness of the cornea becomes edematous in about seven hours. At 24 hours, there is an iritis with strands of exudate in the anterior chamber. The limbus epithelium with its pigment begins to slide over the denuded corneal surface. Vessels commence to invade the cornea from all parts of the limbus on the sixth to the eighth

* Presented as part of a lecture to classes attending the Medical Field Service School, American School Center, European Theater Operations, United States Army.

day. The eye usually perforates in two to five weeks (fig. 2).

REPORT OF CASE

A white man, aged 26 years, was splashed in the right eye with a mixture of arsenic trichloride with small quantities of mercuric chloride, hydrochloric acid, and lewisite. His eye was very painful. He jumped immediately under a shower and his eye was thoroughly irrigated for about 12 minutes. BAL solution or ointment was not available. The patient was hospitalized altogether for about 10 weeks. There is now a dense leukoma and pannus formation over about half the cornea with diffuse nebular haziness of the remaining corneal tissue (fig. 3). There are dense anterior synechiae between the scar and the adjacent iris. The visual acuity is light perception and projection only, whereas the visual acuity in the opposite eye is 20/30.

Treatment. Although most liquid chemicals can be mechanically removed from the eye by immediate irrigation with water, lewisite is one of the exceptions. Lewisite apparently enters into combination with tissue cells so rapidly that it can be removed or destroyed only

by chemical neutralization. Fortunately, the latter can be accomplished by means of an antidote developed by the British and called BAL (British Anti-Lewisite).

BAL should be used as soon as possi-

Fig. 3 (Uhde). Human eye splashed with a mixture of arsenic trichloride and small quantities of mercuric chloride, hydrochloric acid, and lewisite, showing leukoma and pannus formation.

ble after injury. If BAL is used within two minutes after contamination, a short period of disability with complete cure can be expected. The period of disability will be increased but complete cure may result if BAL is used within the first five minutes (fig. 4). The period of disability and the final damage increases markedly with any further delay between contamination and treatment (figs. 4, 5, and 6). For instance, in a series of experiments carried out by the author and Lt. Comdr. R. Leishman (R.N.V.R.) with one tube of BAL ointment, treatment at the end of two minutes neutralized the destructive effect of lewisite so that within 10 days, 100 percent of the eyes were normal; with treatment at five minutes, 77 percent were cured; whereas, at 30 minutes the cures dropped to 33 percent. These latter figures make it quite evident that treat-

Fig. 4 (Uhde). Rabbits' eyes showing that the period of disability is increased (and the final damage) as the interval between contamination and treatment is prolonged: a, Treated with BAL ointment 5 minutes after contamination with a destructive dose of lewisite, appearance on the 7th day, almost complete recovery. b, Treated with BAL ointment 15 minutes after contamination with a destructive dose of lewisite, appearance on the 7th day, keratitis. c, Treated with BAL ointment 20 minutes after contamination with a destructive dose of lewisite, appearance on the 7th day, severe keratitis.

ment may be worthwhile in an occasional eye even after a fairly long interval. Therefore an injured eye should be treated even if as much as an hour has elapsed after contamination.

BAL ointment replaced the original solution because during an emergency most of the solution is spilled. It is much easier for a soldier to instill an ointment

than a solution into his eye, especially if he is in a prone position.

Instructions for the use of BAL issued to each soldier in the European Theater Operations were as follows: In any painful splash of the eye, break off the tip of the BAL tube, place BAL on an index finger, massage the ointment firmly between the lid margins by pulling down

Fig. 5 (Uhde). Rabbit's eye contaminated with 0.0002 c.c. of lewisite, treated 10 minutes later with BAL ointment, appearance 22 days later. Fig. 6, Each eye of rhesus monkey contaminated with 0.0002 c.c. of lewisite, right eye treated 15 minutes later with BAL solution, left eye untreated, appearance at 3 months.

the lower lid so that the ointment goes into the eye. Then place the remaining ointment into the eye, close the lids, and rub the ointment firmly into the eye and lids.

An important problem confronting officers responsible for the treatment and training of personnel was: How is the soldier going to know whether to irrigate or use BAL ointment? The ideal solution would be to have a single ointment equally effective against both mustard and lewisite. Unfortunately, this is not possible at present.

The soldier was instructed to irrigate his eye immediately after any painless, "watery" splash. Immediate irrigation is by far the most effective treatment against a mustard splash.

In any painful liquid contamination of his eye, the soldier was instructed to use BAL ointment.

What about the treatment of a 50/50 mixture of lewisite and mustard gas, which is also painful? It was found experimentally that the best results in such combinations were obtained by the instillation of BAL ointment. The most logical procedure would seem to indicate immediate irrigation to remove the mustard gas and then the instillation of BAL to counteract the lewisite. However, numerous experiments carried out refuted this belief. The best results were obtained by the simple instillation of BAL. There are two possible explanations of this result: (a) BAL is very irritating and produces severe tearing, which may act nearly but not quite so effectively as sim-

ple irrigation in the removal of the mustard; and (b) 0.0002 c.c. of lewisite destroys a rabbit's eye, whereas it usually takes three or four times as much mustard to result in similar destruction. In a 50/50 mixture, therefore, the lewisite is doing more than its proportional share of damage. In other words, the amount of mustard present in such a mixed droplet will usually not, by itself, produce any serious effect in any eye. Moreover, Dunphy has shown that BAL ointment alone, if used within one minute, will save a majority of mustard-contaminated eyes, probably, again, as a result of the irrigating effect of the flow of tears caused by the irritant properties of BAL.

What about a painful liquid-tear-gas contamination of the eye? Prof. Ida Mann has shown that BAL ointment does not increase the severity of such a lesion although Bal is very painful in a normal eye.

When the soldier is in doubt he should instill BAL ointment.

To reiterate, the soldier in the European Theater Operations was instructed to irrigate immediately in any painless, "watery" splash of his eye and to use eye ointment (BAL) in any painful splash or when in doubt.

SUMMARY

The clinical features and treatment of arsenical eye burns are discussed and illustrated with photographs and a case report.

3181 S.W. Marquam Hill Road.

A DEVICE FOR GROUP DEMONSTRATION OF ASTIGMATISM TESTS*

WILLIAM H. CRISP
Denver, Colorado

There is wide variation in the capacity of different individuals for visualization of geometric and other mathematical processes. Even in the most mathematically inclined, the power of visualization is greatly improved by direct experience, or at least by careful study of pictorial illustrations. Any one of these contacts demands thought as well as vision, but mere verbal description reaches the brain a good deal more slowly and vaguely than does pictorial demonstration or solid reality.

Many refractionists have a relatively feeble notion of what goes on in the patient's brain during tests for astigmatism. The nature of tests with astigmatic dials is easier to apprehend than that of tests with the cross cylinders. It was to bring the latter group of tests more effectively to the understanding of workers in refraction that I presented my photographic picturization of the subject to the Washington International Congress of Ophthalmology in 1921.

Several years ago it occurred to me that the new projectors for use with 35-mm. film, with their relatively small objective lenses, should be capable of providing an improved method for demonstrating astigmatic tests, especially those tests in which letters and astigmatic dials are used in combination with cross cylinders. What I had particularly in mind was the placing of minute photographic reproductions of the various charts in the usual position for projection—that is, between the light condenser and the objective lens—and then rotating or “flopping”

the cross cylinder, not behind the objective lens of the projector but immediately in front of it—between it and the screen.

The convenient performance of such manipulations demands the setting up of a small apparatus beyond the objective lens, and it was only after much delay that I finally proceeded to work out the construction of a suitable mechanism. This consists of a carrier in which may be inserted a simple cylinder at a selected axis and another cylinder which perfectly or in various degrees of imperfection corrects the astigmatism created by the first cylinder, and then in front of these simple cylindrical lenses a fixed, semicircular metal arm on which can be supported a cross cylinder capable of the same manipulations as are employed in testing a patient's eyes.

The first, posterior, simple cylinder is used to make the projection lantern astigmatic. Take, for example, a plus 0.50D. cylinder at axis 90°, which will render the apparatus astigmatic in the horizontal meridian. The anterior simple cylinder may then be primarily of either inadequate, adequate, or excessive strength and may be placed at any incorrect or at a finally correct axis. The cross cylinder on the metal carrier is flopped into the usual two positions in testing for amount of cylinder, or the usual two positions in testing for axis of cylinder. The primary astigmatic effect upon test letters or upon astigmatic dials will be first projected on the screen, and the effect of partial or of exact correction or of overcorrection can be shown, either with the anterior simple cylinder or with this in combination with the manipulations of the cross cyl-

* Read at the eighty-first annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, November, 1945.

inder. Or the cross-cylinder test for correct axis may be carried through all the manipulations used upon the patient, varying the position of the more or less correcting simple cylinder and displaying, in accordance with the rules of the game, the effect of the changing positions of the cross cylinder.

Apart from the irregularities of the human eye, certain optical complications of the use of the projection lenses interfere moderately, but only moderately, with the complete accuracy of the scheme. However, its effect is close enough to accuracy to allow of furnishing an excellent illustration of what is seen by the patient in the various tests. It is my thought that, in institutions where the formal teaching of refraction is undertaken, much might be gained for graphic presentation of the subject to groups of students. My own appa-

Fig. 1 (Crisp.). A device for group demonstration of astigmatism tests.

ratus is crude but sufficiently effective to serve the purpose.

(The author personally demonstrated upon the screen, using an S. V. E. 35-mm. projector, the various manipulations referred to in his paper.)

530 Metropolitan Building (2)

DISCUSSION

DR. JOHN GREEN (St. Louis): The present wide popularity and almost universal use of the cross cylinder by American ophthalmologists is due, in very large measure, to the enthusiastic advocacy by Dr. Crisp of the unique value of the method in insuring high accuracy in the subjective measurement of the refraction. His careful descriptions of the technique, supplemented by drawings and photographs, have made the practical steps in the process completely understandable.

Dr. Crisp states that "many refractionists have a relatively feeble notion of what goes on in a patient's brain during tests for astigmatism." I am convinced, too, that ignorance of what goes on in the patient's eye during manipulations with the cross cylinder is fairly widespread,

and this despite the clarification of the subject by both Jackson and Crisp.

I am not entirely in agreement with the author's statement that "the nature of the tests with astigmatic dials is easier to apprehend than that of tests with the cross cylinder." This view may be valid when dealing with keen and highly intelligent patients. Given a patient with a not too bright mentality (a little above the level of Mortimer Snerd but below that of Charlie McCarthy), it has seemed to me that I have to devote an unconscionable amount of time in attempting to get consistent answers to the query "which are the most distinct lines in the chart?"

I use a modification of Lancaster's chart in the form of a fan, with the lines at 10° intervals (21 radii in all), and I have

my nurse at the first signal from the patient place a black pointer at the outer termini of the radii primarily selected. After a rest interval (with the patient in semi-darkness and suitably fogged) reëxamination will sometimes yield answers inconsistent with those given primarily.

I have found it useful (though time consuming) to dislodge the patient from his chair and to walk him up to within 5 ft. of the chart while I deliver a little lecture on the beauties of the astigmatic chart when all the lines are uniform in appearance.

No one can deny the beauty of Dr. Crisp's demonstration, which he has devised for group instruction. Might it not also be used as a preliminary exercise for patients about to undergo the test? The demonstration could be conducted by the technician, so that the patient thus instructed would be reasonably familiar with the changes wrought in test letters and astigmatic charts when seated at the test range.

I hope Dr. Crisp may develop his device to illustrate pictorially the vagaries and aberrations of the accommodations, disregard of which is all too common in the hurried and mass refractions of busy offices and busier clinics.

DR. WALTER B. LANCASTER (Boston): I think the method of projection is very valuable, and I used the method of projection before this Society some years ago in demonstrating astigmatism with a projector. What I wish to call attention to today is the fact that most of the methods used are qualitative and not quantitative. I mean by that, the aberration produced on these letters by an 0.25D. cylinder is not quantitatively comparable to that produced in the human eye. Many years ago Hess published some photographs of pages of print as they appeared to the camera made astigmatic with a cylinder

lens. I do not remember what strength cylinder he used, say 0.5D., and the print was almost illegible. We know very well that 0.5D. before the normal human eye does not produce any such illegibility. I think Dr. Verhoeff also reproduced some print with a camera made astigmatic but without making quantitative comparisons.

I showed before this Society, when Dr. Prangen was presenting a paper on the conoid of Sturm, the method of projecting the conoid with a lantern, and showing the amount of astigmatism produced by a small astigmatic lens, 0.25D. In my paper before the Academy in 1915, I went into the question of photographing the test objects with a camera made astigmatic, and I should like to show the results.

In the figure, p is the pupil or aperture; r is the retina = the focus of the emmetropic eye; f is the focus when $-0.25D.$ cylinder is added; d is the diffusion circle (line if the cylinder is used) on the retina. The magnitude of the blur depends on three things: (1) on the size of the pupil; (2) on the ratio the distance from the retina (where the blur circle is) to the focus bears to the distance from the pupil to the focus (this ratio is $df : pf$); and (3) on its effect on the magnification of the image by the lens system—if the system magnifies five times as much it will tolerate five times as large a diffusion circle with comparable blurring effect.

df is the distance in millimeters of the focus behind the retina when the eye is made hypermetropic by a minus lens, in this case $-0.25D.$ cylinder. It is calculated as follows: The focal length of the eye when the focus is on the retina may be taken as 22 mm. = 45.45D. When the $-0.25D.$ cylinder is added this becomes 45.20D. = 22.12 mm. The new focus is therefore -0.12 mm. back of the retina,

$df = 0.12$. The ratio of df to pf is $0.12 : 22.12 = 1 : 184$.

In the case of the camera, the focal length (if a 6D. lens system is used) is 166.7 mm. When $-0.25D.$ is added, this becomes $5.75D. = 173.9$ mm. The value of df is $173.9 - 166.7 = 7.2$; $df : pf = 7.2 : 173.9 = 1 : 24$.

Thus the blur in the eye is $1/84$ of the pupil diameter 4, which equals 0.021 mm. The blur in the camera is $1/24$ of the aperture; if the aperture is 20 mm. the blur equals 0.833 mm. The blur circle (line) is 40 times as large in the camera as in the eye, supposing apertures of 20 for camera and 4 for eye. How much should we allow for magnification of image? The image size for an object at a given distance depends solely on the distance from the nodal point to the retina or film. In the eye it is 17 mm. from nodal point to retina; in the camera it is 167 mm. from nodal point to film. Thus, the camera image is 10 times as large as the eye image. If one wishes the camera to have a blur circle (or line) comparable to the eye, it must reduce its blur to 10 times that of the eye instead of 40 times. This is readily accomplished by reducing the aperture to one fourth its former size of 20 mm. With an aperture of 5 mm. the camera with a 6D. lens system would give images whose blur would be comparable quantitatively to the blur in the eye with an $-0.25D.$ cylinder. By a similar calculation, quantitative results could be obtained with a camera of a different focal length of lens. The same is true of a lantern.

Why not do this when demonstrating to an audience or class so that they may get a true and correct idea of what a .25D. lens produces in the way of blur?

DR. F. H. VERHOEFF (Boston): For illustrating his paper on astigmatic charts, Dr. Lancaster employed an ordinary photographic lens corrected for aberrations.

In spite of the employment of a corrected lens, Dr. Crisp's apparatus is very useful for instructing a group of students who know little about the subject of refraction. It would be a difficult matter to construct an apparatus that would simulate the optical defects of the normal human eye. I have never thought it worth while to attempt to do so. For each individual student has an optical apparatus of his own, his eye, which we may use for teaching purposes. If its refraction is normal, we can make it abnormal as desired by means of spheres and cylinders.

DR. W. H. CRISP (closing): The point that Dr. Lancaster emphasized as to the relatively large aperture in the human eye is an important one. Many of you who do photography are familiar with the F system for indicating the relative size of the lens aperture. Suppose you have a half-inch lens and a $5\frac{1}{2}$ -inch focal length, that is $5\frac{1}{2}$ divided by 0.5, which gives F 11; while in the human eye suppose you have a 4-mm. pupil and a distance back from the diaphragm to the retina of at most 20 mm. Then you have a ratio of 1 to 5, making F 5, quite a large opening. All these demonstrations are rendered somewhat unsatisfactory by the fact that we get a very much greater difference in the camera than in the human eye. In other words, in this respect the human eye is a more beautiful optical apparatus than the camera, although the camera is better in other respects.

I have here a supplemental note with regard to the apparatus. Tried on different lanterns, one becomes conscious of some differences of effect as between different projectors. With a high-class anastigmatic lens, the effect may show less satisfactorily than with a cheaper outfit. The effect on the projection of certain astigmatic dials is at times almost as paradoxical as that of astigmatic dials on some

patients. Used with the letters, however, it demonstrates some of the difficulties which patients experience in answering questions.

Some letters, on account of their shape, are so distorted as to suggest a somewhat different judgment on the part of the patient than other letters, which is in harmony with the fact that, generally speaking, it does not pay to ask the patient to concentrate on a single letter but it is better to have him base his judgment on a survey of a whole line of letters as distorted by the cross cylinder in its two po-

sitions. We are also given an illustration of the fact that the patient can sometimes make a more definite decision if he is looking at the larger letters instead of at the smallest letters he is able to read. We also realize the need for instantaneous reversal of the position of the cross cylinder, without an interval in which the patient can be distracted by the more normal intervening appearance of the letters. The device shows fairly well the frequent emphasis on the vertical parts of letters in one position and on the horizontal parts in the other position.

CULTIVATION OF HUMAN TUMOR IN THE ANTERIOR CHAMBER OF THE GUINEA-PIG'S EYE*

EUGENE M. BLAKE, M.D.
New Haven, Connecticut

The general pathologist and the worker in the field of cancer research are thoroughly familiar with the experiments of Dr. Harry S. N. Greene, professor of pathology at the School of Medicine, Yale University, who has succeeded in the transplantation and growth of embryonic tissue and various mammalian and human tumors into the anterior chamber of laboratory animals. It is doubtful, however, if the clinical ophthalmologist is conversant with this work. So, because of the opportunities this method presents to study numerous problems of interest to the latter, the writer has asked permission to report a few of the outstanding developments of Dr. Greene's work and to present the results of a small problem undertaken under his guidance.

As early as 1882, Fischer¹ transplanted pieces of rib and ensiform process from human embryos into the wattles of hens,

and reported growth of the transplants. Since that time many investigators have attempted, with more or less success, the homologous and heterologous transplantation of different tissues into various parts of experimental animals. After many other approaches to the problem, Greene found that the anterior chamber provided the best site for the study of such transplants, both because of higher percentage of takes and because the growth of the transplant can be watched from day to day with the naked eye and under magnification. The animals used have been rabbits, swine, goats, and guinea pigs. Of these the rabbit, and especially the guinea pig, were found best adapted to this purpose.

Only a few of the interesting developments of this work need be related, but it is desirable to present them because of their intrinsic value and to form the background of the side experiment on the progressive growth of the human tumor tissue in the anterior chamber of the

* Read at the eighty-first annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, November, 1945.

guinea pig, which is the subject of this communication.

Transplantation is performed under local anesthesia, using a few drops of 5-percent solution of cocaine hydrochloride. An incision is made at the limbus above, by thrusting a double-edged knife through this tissue into the anterior chamber. A portion of the aqueous is allowed to escape and a piece of tumor, about 1 mm. in size, is inserted into the chamber by means of a trocar. By gently stroking the cornea this transplant is worked down to the lower angle of the chamber. No sutures are employed, and infection is very rare. An instance of homologous transplantation is that of an adenocarcinoma of the rabbit uterus into the anterior chamber of other rabbits.² In such transfers, 90 percent of the transplants take, and growth is usually evident during the second week. The chamber is usually filled by the 30th day. Regression of the growth occurs in 70 percent of the eyes, but in the remainder growth is progressive, and metastases occur after 6 to 8 months. Heterologous transplantation to guinea pigs, goats, and swine has also been effected, utilizing the same inoculation sites, and the tissue has been carried by serial passage for many generations in the foreign host.

As a rule it is possible to tell if a take has occurred by the second week, but at times as long as 110 days are required before growth becomes evident. Growth is manifested by an increase in the size of the transplant and the development of a pinkish color. Occasionally, the anterior chamber is completely filled by the 15th day, but more often 6 to 7 weeks pass before the transplant attains this size. Rarely is growth extremely slow, but in one instance the tumor had increased to only 2.5 mm. in size after a period of 785 days.

At autopsy the findings are consistent: The growth is seen as a pinkish, semi-

translucent mass. The fast-growing tumors are attached to the iris over only a small area, resembling a polyp, whereas the slow-growing tumors invade a large part of the iris, replacing the stroma. The cornea is occasionally invaded, and the growth may extend into the vitreous. Microscopically, the heterologous transplants are much like those of homologous transplants. The epithelial cells are identical and show the same tendency of arrangement. No lymphocytic infiltrations and scant changes suggestive of a foreign-body reaction are observed. Results similar to these changes are observed on transfer of a variety of other tumors from the rabbit to the guinea pig eyes.

The success obtained by using the anterior chamber as a transplantation site for heterologous tissues is in sharp contrast to the complete failure of transfer to other bodily regions and requires some comment. In other inoculation sites, the introduction of tissue from a foreign species is followed almost immediately by an intense inflammatory reaction which terminates either in abscess formation or in encapsulation and necrosis of the transplant. On the contrary, no immediate reaction follows the transfer to the anterior chamber. The implant remains without visible change for several days and may even undergo a slight increase in size before vascularization occurs. It seems probable that during this period the tumor stroma, representing normal tissue from the donor, dies and disintegrates. The parenchymal cells, on the other hand, representing essential tumor elements, continue to live, obtaining nutrient from the surrounding media in the manner of a tissue culture. When, eventually, the delayed reaction in the iris occurs, the implant consists only of essential cancer cells which have no species identity, and the reaction is comparatively mild, resulting in vascularization of the graft, rather

than encapsulation, as in other regions.

The ability to survive and grow in the anterior chamber of an alien host is a property common to cancer and embryonic tissue, and this property is not shared by normal adult tissue or benign tumor tissue.

Among many other interesting experiments done by the same investigator^{3, 4} were those in which transplantation of heterologous embryonic human and other mammalian tissues into the anterior chamber of guinea pigs and rabbits was successful. This ability to transplant human embryonic tissue to lower animals offers a new approach to many medical problems and is being widely employed in cancer research. Greene transplanted into the anterior chamber, in whole or in part, many individual organs taken from 10- to 30-day-old human embryos, including lung, brain, heart, stomach, intestine, and kidney. The results of brain- and lung-tissue transplantation are especially interesting. For instance, portions of cerebral cortex often grow with well-marked convolutions and gyri, which suggests that such formations are not entirely due to restricted space in the skull.

Certain changes in the eye which were reported in Greene's papers are particularly worth noting. Thus, in some of the eyes containing transplants of acinar-type breast tumor,² the cornea ruptured as the result of increased pressure, and the tumor protruded through the perforation. When this occurred, infection and regression often took place. In other instances, tumor tissue extended under the conjunctiva and invaded the vitreous chamber. The iris was always infiltrated with tumor cells, and the ciliary body was usually involved. Whereas the tumor cells extended under the palpebral conjunctiva in the older growths, the muscle of the eyelid was never invaded, nor were metastases found. In the human-fibrosarcoma trans-

plants, invasion of the iris occurred early and resulted eventually in protrusion through the iris, with occupation of the posterior chamber. Sometimes after filling the anterior chamber, partial regression was observed together with survival of cells in a particular portion, so that following a period of regression, renewed growth occurred, and the chamber was again filled with tumor.

In the case of a spontaneously developing skin carcinoma of the rabbit⁵ which was transplanted into the anterior chamber of other rabbits, it was noted that the tumor grew rapidly and that glaucoma developed early. This always resulted in premature regression of the tumor. It was also noted in the case of developing embryonic rabbit tissue⁴ that regression of the growth followed filling of the chamber, and that this appeared to be the result of progressive diminution of the blood supply incident to increased intra-ocular pressure. In two other instances, rupture of the chamber in the region of the healed corneal incision developed. In both of these the transplant consisted of developing human feet. Growth was rapid from the first, with elongation of the toes and metatarsals. The shape and structure of the feet were retained until the chamber filled, when deformation of structures occurred. In one case of human fibrosarcoma transplanted to the guinea pig's anterior chamber, interstitial keratitis and glaucoma developed⁶ so that by the 220th day the corneal opacity obscured the graft to such an extent that further observation was impossible.

One of the phases of the problem of growing transplanted heterologous tumor tissue which has not been specially considered, so far as is known, is the progressive development of the transplant within the new host. It was, therefore, determined to implant fragments of human tumor tissue—in this case, the fibro-

sarcoma, whose histologic characteristics were known—into the anterior chamber of a number of guinea-pig eyes and to remove the eyes at progressive stages of development of the tumor. It was at first planned to enucleate the eyes at stated intervals of time, but it was found that

sumed a pinkish hue, indicating the development of newly formed blood vessels. The tumor then increased in size, sometimes rapidly, sometimes more slowly, until it finally filled the anterior chamber. At this stage there was seen a regression of the tumor, or increase in size,

Fig. 1 (Blake). Section of fibrosarcoma from human breast.

the rate of growth was not predictable nor regular, because of factors not too well understood. Therefore, it was found better to remove the eyes when the visible growth had progressed to appreciable differences of size, and to disregard the time factor.

The tumor chosen for study was a fibrosarcoma removed in March, 1940, from the breast of a woman aged 20 years. It has been transplanted through many generations in the anterior chamber of the guinea-pig eye (fig. 1). The cells of this tissue are moderately large, with large nuclei, generally elongated, and with considerable intercellular substance. The cells show a pronounced tendency to arrangement in fascicles, some of which surround blood vessels. The fascicles cross and interlace feebly.

After the transplant was introduced into the anterior chamber, it remained without visible change for from a few days to two weeks. At this time it as-

sumed a pinkish hue, indicating the development of newly formed blood vessels. The tumor then increased in size, sometimes rapidly, sometimes more slowly, until it finally filled the anterior chamber. At this stage there was seen a regression of the tumor, or increase in size,

which finally eroded the cornea, and the growth appeared as a fungating mass. The implant always attached itself to the iris, and when vascularization de-

Fig. 2 (Blake). Early growth of implant into anterior chamber of guinea-pig's eye.

veloped, it arose from this structure. The invasion of the iris was rapid, the latter becoming considerably thickened and swollen. If the guinea pig was heavily

pigmented, the iris pigment proliferated and became part of the new growth, being more apparent in the posterior portion of the tumor, in closest proximity to the iris.

Figure 2 shows an early growth of the implant, which in this case did not

reach the angle of the anterior chamber but evidently became caught between the iris and the cornea. Anteriorly, Descemet's

Fig. 4 (Blake). Bilobed tumor of iris of guinea pig.

met's membrane is still intact, but in places the endothelial cells are lost. The substantia propria is not invaded. The principal mass is sarcomatous tissue that resembles the original tumor in all respects. At one point, posteriorly, the involved iris has come into contact with

the lens capsule, a portion of which can be seen broken off and adherent to the tumor cells. There is inflammatory reaction in the lens, and the fibers are separated by leukocytes and lymphocytes. There is some free blood in the posterior chamber.

Figure 3 is a good illustration of the manner in which a rapidly growing implant springs from the iris in a polypoid mass. The iris on one side of the section is normal, whereas on the opposite side one sees the tumor arising from the iris near the angle, coming into contact with the cornea at one point, and extending slightly beyond the pupillary border. A small strip of Descemet's membrane is peeled off and the tumor cells are begin-

Fig. 5 (Blake). Anterior chamber filled by sarcoma.

ning to invade the stroma. On the posterior surface, the tumor lies against the lens capsule but has not penetrated this membrane. There is a foreign-body reaction in the iris at the point of origin of the implant.

In figure 4 there is seen a bilobed tumor mass which arose from the iris on one side and extended around the pupillary border to involve the opposite half of the iris. The tumor mass is highly vascular, and some of the blood-vessel walls are well developed. Again the tendency to strip off Descemet's membrane is seen. There is early invasion of the ciliary body.

Figure 5 shows an eye in which the anterior chamber is entirely filled by the growing tumor cells. The posterior surface of the iris can be plainly followed because of the pigment layer, and the site of the pupil is indicated by the gap between the pigment layer on each side of the figure. The tumor cells have extended through the pupil into the posterior chamber and have destroyed the lens capsule in this area and progressed between the lens fibers. Anteriorly, the cornea is thinned in the central area, and tumor cells have entered the stroma.

In figure 6 we see an eye which is almost entirely filled with the tumor. The cornea is a little thinned but has withstood the pressure of the growing mass unusually well. The sclera, as always, has resisted invasion. The lens has been

Fig. 6 (Blake). Globe filled by tumor.

displaced backward by the tumor until it is in contact with the sclera at the posterior pole. The retina is edematous and degenerated but not infiltrated with tumor cells. The bundles of tumor cells are characteristic of the original tumor of the breast.

Figure 7 shows a fungating mass in a disorganized globe. Anteriorly, as in every part of the eye, great changes have

taken place. At the periphery of the cornea the superficial epithelial cells are keratinized, and the deeper cells edematous. Beneath this, between the epithelium and the stroma, is an extensive hemorrhage. Nearer the center of the cornea, the

Fig. 7 (Blake). Disorganized globe with fungating mass.

tumor cells have invaded the epithelium, and, at the center, they have ruptured through and lie on the surface, mixed with polymorphonuclears. The stroma is swollen, and there are sarcoma cells scattered throughout, with many islands of blood and areas of necrosis. Descemet's membrane has entirely disappeared except for two or three short strands. The iris and ciliary processes are suggested only by pigment streaks, and the tumor fills practically the entire cavity of the globe. A few isolated bundles of lens fibers are found, but the lens has almost completely disappeared. The globe is filled with sarcoma cells, areas of infection,

and hemorrhage. At the posterior pole is a staphylomatous protrusion containing the tightly coiled retina and blood. The external limiting membrane is preserved in places. A portion of the optic nerve is seen at the tip of the staphyloma and is not invaded by tumor cells.

Figure 8 shows a section of the tumor taken from the globe described in figure

arising in the human eye may aid in furthering our knowledge of the pathology of these growths. Such experiments are already under way. The study of pigment formation may be aided by the use of the anterior chamber, for we know that a pigmented sarcoma transplanted into the eye of an albino pig continues to grow pigment, showing that the ability to pro-

Fig. 8 (Blake). Section of fibrosarcoma taken from tissue from figure 7, showing identity of the original and transplanted tumor.

7 and is of the same cytologic characteristics as the original implant taken from the patient's breast (fig. 1).

The purpose of this presentation is not primarily to show the development of a transplant of human fibrosarcoma into the anterior chamber of the eye of the guinea pig, but to call attention to the possibilities of the utilization of the anterior chamber of laboratory animals for various research problems. Since human embryonic tissue will develop in this cavity, it should be possible to study here the growth of different embryonic tissues of the eye, as well as of other portions of the body. The ability to grow tumors

duce pigment resides in the tumor cells and not in those of the host. It may be that some of the animal parasites will grow in the anterior chamber and afford an opportunity to observe the changes taking place during their life cycle. These and many other possibilities will suggest themselves for the employment of these easily obtained laboratory animals, where changes may be observed without sacrificing the animal until needed, and where, with the naked eye or under magnification, one may follow the changes taking place.

DISCUSSION

DR. L. T. POST (St. Louis): I am interested in this paper because in my candidate's thesis for the American Ophthalmological Society, published in the Transactions for 1924, incidental to work with the thermophore on which the essay was based, I transferred the so-called Jensen sarcoma into the anterior chambers of white rats and treated it with the thermophore at 160° for 1- and 2-minute corneal applications. In about 30 percent of the cases, the tumor continued to grow, and in most of these, if the tumor had not extended too far, the thermophore destroyed the growth. The principle has had practically no therapeutic application, except in one case of Dr. William Luedde's. The patient had only one eye and many ophthalmologists concurred in the diagnosis of melanotic sarcoma of the anterior segment of the choroid. Since the patient would not consent to removal of the eye, Dr. Luedde used the thermophore and followed the patient for many years thereafter. The last I heard about it, the patient still had the eye, and the growth had regressed. Further studies with human tissue should be made and different types of therapy tried. However, this is not by any means advocating the use of the thermophore in the treatment of intraocular tumors.

DR. BERNARD SAMUELS (New York): Dr. Blake has called attention to the experimental work that is being done by the general pathologist in the implantation of tumor and embryonal tissues in the anterior chambers of animals. He has given the results of an independent experiment of his own, undertaken for the purpose of observing the manner of growth and regression of fragments of a fibrosarcoma after they had been transplanted into the anterior chamber of guinea pigs. I agree with his theory that those elements in an implanted tumor that represent normal

tissue disappear so that only malignant cells are left to propagate. The slowness, that he observed, with which the infiltrating type grew in the iris was probably largely due to the mechanical resistance offered by the normal stroma to the advance of the proliferating tumor cells. In man, slow growth is characteristic of the infiltrating type of a primary malignant melanoma anywhere in the uveal tract. Dr. Blake noted that the pedunculated-shaped implants grew rapidly. This was due to the fact that the tumor cells were disposed in a fluid medium in which the resistance was not so great as in the iris stroma, and, furthermore, the resistance being equal in all directions, the mass assumed a globular form.

There are but two primary intraocular tumors of great importance—the malignant melanoma and the retinoblastoma.

To supplement Dr. Blake's observations, I should like to throw on the screen several slides that demonstrate the behavior, in the early stages, of fragments of primary intraocular tumors in man, once they are disseminated into the cavities of the globe. I should like to call attention also to one slide that shows how lenticular epithelial cells, free in the aqueous over a long period, have been preserved and have proliferated.

DR. EUGENE M. BLAKE (closing): I should like to thank the discussers for their remarks, and to say one thing that I think is important, and that is that it may be we can use the anterior chamber to determine malignancy. For instance, in a case of sarcoma of the soft palate of a Negro, in which portions of the tumor, implanted in the eye of guinea pigs, died in every instance, but when, within a few months, metastases occurred in the neck and portions of these were implanted in the anterior chamber, they grew in 100 percent of the animals. It might be pos-

sible to divide these tumors into the stage of dependency, when they are dependent on their host for growth, and the stage of autonomy. When they reach the stage

of autonomy, they will grow in the anterior chamber of a foreign host, and apparently will not do so in the stage of dependency.

CORNEAL ULCER TREATED WITH STREPTOMYCIN*

NORBERT F. ALBERSTADT, M.D., AND ALISON HOWE PRICE, M.D.
Philadelphia

The use of streptomycin hydrochloride in the treatment of corneal ulcers was suggested because of the ability of this antibiotic to inhibit the growth of both gram-negative and gram-positive bacteria. Waksman and his associates isolated two related substances, streptothricine¹ and streptomycin.² Streptomycin, obtained from a strain of *Actinomyces griseus*, is less toxic, and we used this to treat patients with corneal ulcers. Because of the limited supply of streptomycin, only those who had received previous treatment but with unsatisfactory results were classified under the category severe corneal ulcer. In order to test the possible added value of the drug as compared with the results from the usual form of treatment, nine patients with corneal ulcer were given streptomycin as an adjuvant to the routine treatment with atropine sulfate, hot compresses and, occasionally, typhoid vaccine. The control group was 13 patients with corneal ulcer who failed to respond to treatment in the out-patient department and required hospitalization. The severity of their condition was comparable to that of the patients treated with streptomycin.

The criteria were (1) duration of pain; (2) healing time of the ulcer; (3) total days of hospitalization.

Streptomycin hydrochloride[†] was used in a concentration of 10,000 units[‡] in each c.c. of normal salt solution. Two drops were placed in the affected eye every two hours day and night.

CASE REPORTS

Case 1. P. D., a white man, aged 57 years, was admitted on June 29, 1945, because of pain in his left eye beginning five days prior to admission. Vision was 6/15. There was mild edema of the upper lid and severe conjunctival injection of the left eye. The cornea was diffusely hazed throughout, and a corneal ulcer, 3 mm. in diameter was observed at the 2-o'clock position, 1½ mm. from the limbus. The ulcer stained heavily with fluorescein. Slitlamp examination revealed the depth of the ulcerous invasion as one-half the thickness of the cornea. There were numerous folds and wrinkles in Descemet's membrane, especially in the area of the ulcer.

Treatment. The following medication was ordered for the left eye: a 1-percent solution of atropine sulfate, 2 drops three times a day; hot compresses for 20 minutes four times a day; and 2 drops of streptomycin every two hours day and

[†] All of the streptomycin used was supplied through the courtesy of Merck & Company, Inc., Rahway, New Jersey.

[‡] One unit represents 1 microgram in terms of weight of pure streptomycin base according to the newly adopted plan.

* From Wills Hospital and Jefferson Medical College.

night. By the second day of treatment the ulcer was improved; only its temporal portion stained with fluorescein. The slit-lamp examination revealed clearing throughout the cornea with a smoothing of the epithelial folds. There was less pain. On the third day there was much diminished redness of the eye, the pain was gone, and only a small island of the ulcer still stained. On the fourth day the ulcer no longer stained; and by slitlamp examination only a small depression was observed to remain in the mid-portion of the healed ulcer. The use of streptomycin was stopped after six days' treatment. The patient was discharged symptom-free, with vision of 6/12. Three weeks after discharge the patient was seen in the clinic and there remained only a small nebular opacity that appeared to be clearing.

Case 2. T. J., a colored man, aged 53 years, was admitted on July 9, 1945. The patient had been well until three days prior to admission, when he developed lacrimation, photophobia, and pain in the right eye. The vision of this eye was 6/60 corrected to 6/30. Edema of the upper lid and conjunctival injection of the right eye were marked. There was a large ulcer at the 6-o'clock position, 3 mm. in size and 2 mm. from the limbus. Several deep opacities at the limbus, at the 6-o'clock position, were due to a previous perforating injury. Slitlamp examination confirmed the size of the corneal ulcer and showed it to be superficial. The cornea was hazy throughout.

Treatment. Medication prescribed for the right eye was: a 1-percent solution of atropine sulfate, 2 drops, three times a day; hot compresses for 20 minutes, four times a day; 2 drops of streptomycin, every two hours day and night. Two days after treatment was instituted, there were only very small punctate areas of staining

present within the ulcerated area, but the pain, most of the lacrimation, and swelling of the lids had subsided. On the fifth day there was no staining, photophobia, or pain. After nine days' treatment with streptomycin, the patient was discharged symptom-free, with the cornea clear except for the deep opacities observed as due to a previous injury. Vision was 6/60 corrected to 6/30.

Case 3. J. D., a colored man, aged 29 years, was admitted on July 20, 1945. Two months prior to admission, the right eye felt scratchy, and a hair was removed; but the symptoms became gradually more severe. The patient was treated as an outpatient for three weeks, but received no alleviation of his symptoms. Vision was 6/15 corrected to 6/9. There was marked epiphora of the right eye, with an edema of the lids that gave the impression of a partial ptosis. Conjunctival edema and injection were likewise severe. The corneal ulcer was 3 mm. in size and was located at the limbus at the 7-o'clock position, surrounded by a hazy infiltration. Slitlamp examination showed that the ulceration extended into the anterior third of the stroma. There were a few folds and wrinkles in Descemet's membrane in the region of the ulcer.

Treatment with a 1-percent solution of atropine sulfate, 2 drops, three times a day; hot compresses for 20 minutes, four times a day; and 2 drops of streptomycin in the right eye every two hours day and night was instituted. On the second day of treatment with streptomycin, the pain was gone and only the central part of the ulcer stained. The injection and edema of the conjunctiva were greatly reduced. Slitlamp examination showed that the edges of the epithelial portion of ulcer had curled inward toward the cornea and had become smooth. By the fourth day the ulcer did not stain, and

the edema and injection were gone. Following seven days of treatment the patient was discharged symptom-free, with vision of the right eye 6/15 corrected to 6/9.

Case 4. J. G., a white woman, aged 52 years, was admitted on October 5, 1945. Since pregnancy at the age of 34, the patient had had poor vision in both eyes. There was bilateral exophthalmos. The patient fell two days prior to admission and broke her glasses. This accident was followed by pain in the left eye. Vision in this eye was limited to perception of hand movements. Superimposed upon a leukoma at mid-cornea of the left eye was an ulceration, $2\frac{1}{2}$ mm. in diameter, which extended into the stroma and was surrounded by an area of scarring. There was a hypopyon, 2 mm. in height. The patient had hyperthyroidism, which could account for the bilateral exophthalmos. Slitlamp examination of the left eye showed a denuded area which extended into the mid-stroma. Surrounding this there was a leukoma.

Treatment for the left eye consisted in: the instillation of a 1-percent solution of atropine sulfate, 2 drops three times a day; hot compresses for 20 minutes, four times a day; and instillation of 2 drops of streptomycin every two hours day and night. After one day of treatment the pain was not so severe, but the staining was still deep. Slitlamp examination revealed, as in the other cases, that the edges of the ulcer were smooth and curled inward toward the cornea, which was in direct contrast to the rough edges that were curled outward toward the conjunctiva of the lids, noted on the first examination. The hypopyon was reduced to 1 mm. in height. Two days later the hypopyon was gone, but the ulcer still stained. There was no pain. A tarsorrhaphy was performed because of the ex-

ophthalmos, and streptomycin was continued postoperatively through the opening at the medial canthus. Twelve days after the tarsorrhaphy, the sutures were removed. The ulcer had healed, and the patient was symptom-free. Treatment with streptomycin was continued for 16 days. Vision on discharge was 3/60.

Case 5. P. G., a white man, aged 40 years, was admitted on October 2, 1945. The patient had had a corneal ulcer of the right eye in 1942, no residual scar. Four days before admission, the right eye became red and painful. The vision was 6/21. The right eye showed moderate edema of the lids and marked conjunctival injection. The cornea was hazy. The ulcer involved about one third of the cornea and stained deeply. The hypopyon was $1\frac{1}{2}$ mm. in height. Slitlamp examination revealed that the ulcer extended into the posterior part of the stroma and also that there was a small superficial opacity nasal to the ulcer, possibly the residuum of the ulcer of 1942. Wrinkles and folds were present in Descemet's membrane in the area of the ulcer, and there appeared to be active keratitic precipitates.

Treatment. Medication prescribed for the right eye included: 1-percent solution of atropine sulfate, 2 drops, three times a day; hot compresses for 20 minutes, three times a day; 2 drops of streptomycin every two hours day and night; and 1 drop of 10-percent aqueous neosynephrine, three times a day, was added to the treatment to aid in mydriasis. Following two days of treatment the conjunctival injection was only slight, and the hypopyon was smaller. On the third day, the hypopyon was one half as deep, and the pain was gone. There was continued improvement until the fifth day of treatment when, for the first time, fluorescein was noted in the anterior chamber.

Slitlamp examination showed the ulceration healing from the edges with a deep central channel. The patient did not complain of any pain. On the seventh day, no fluorescein entered the anterior chamber. Slitlamp examination revealed the ulcer to be practically healed except for the small central channel. On the eleventh day the central channel was almost closed. On the thirteenth day the patient was discharged symptom-free with ulcer completely healed. Vision was 6/12.

Case 6. I. S., a white girl aged 17 years, was admitted on August 20, 1945. One week before admission the right eye had become red and painful. Vision was 6/21. There were marked edema of the lids, conjunctival injection, and a ciliary flush. The ulceration involved almost the entire cornea. Slitlamp examination showed the ulceration to extend into the anterior portion of the stroma.

Treatment. The patient was treated with atropine, penicillin drops and ointment, typhoid vaccine, and penicillin, 160,000 units intramuscularly each 24 hours. The corneal ulcer failed to respond to this treatment. Paracentesis was performed, medication with penicillin was discontinued; but the use of typhoid vaccine was continued and that of streptomycin was started locally. After two days of treatment with streptomycin, the pain was gone. After 14 days, the area no longer stained with fluorescein and the patient was symptom-free. The patient was examined in the clinic three weeks later. The eye was white; at the site of the previous ulceration there was scarring, which reduced vision from 6/21 to ability to count fingers; there was, however, no activity of the ulcer.

Case 7. W. W., a white man aged 34 years, was admitted on July 21, 1945. The patient had had recurrent corneal

ulcers for the past year. Three weeks before admission, the left eye became painful and injected and failed to respond to the treatment previously prescribed. Vision of the left eye was 6/15 corrected to 6/9. The left eye had moderate conjunctival injection and edema of the lids. There was a large, deeply staining ulceration of the superior portion of the cornea, and many small irregular areas which also stained with fluorescein. Slitlamp examination showed the ulcer to extend into the stroma of the cornea, but the other ulcerations were superficial.

Treatment. The left eye was treated with a 1-percent solution of atropine sulfate, 2 drops, three times a day; hot compresses for 20 minutes, four times a day; 2 drops of streptomycin, every two hours day and night. The pain was gone after 36 hours of treatment. The ulcerations still stained. On the fifth day of treatment only the mid-portion of the corneal ulceration stained. It was thought that intravenous injections of typhoid vaccine would hasten recovery, and these were given every other day. Following 12 days of streptomycin treatment and four febrile crises, the ulcer no longer stained, and the patient was symptom-free. He was discharged; three months later, he had had no recurrence of symptoms, and at that time his corrected vision was 6/9.

Case 8. M. N., a white woman aged 60 years, was admitted on July 18, 1945. Two years before admission, the patient developed a right facial paralysis due to a parotid tumor. This was followed by frequent attacks of epiphora and inflammation of the right eye. Three months before admission, the right eye became red and painful, and there was a mucopurulent discharge. When this did not respond to treatment, the patient was admitted to the hospital. There was a lagophthalmos of the right eye. Vision was

1/60 corrected to 2/60. The conjunctiva was thickened and reddened with marked injection. The corneal ulcer involved the entire cornea and stained throughout. Because of the mucopurulent discharge, very careful cultures were taken, but *Staphylococcus albus* was the only bacteria cultured.

Treatment. Medication prescribed for the right eye was a 1-percent solution of atropine sulfate, 2 drops, three times a day; metaphen irrigations, four times a day, followed by liquid petrolatum; and intravenous typhoid vaccine. The ulcer failed to respond to this treatment, and a median tarsorrhaphy was performed, streptomycin drops being inserted at the medial canthus. Streptomycin was used as previously described. Due to a misunderstanding, the sutures were removed four days later, and this offered an opportunity to stain the ulcer. Only the temporal quarter of the previous ulcer stained. The pain was gone, and there was no longer any mucopurulent discharge. It was necessary to repeat the tarsorrhaphy three times because of failure of the lids to remain in approximation following removal of the sutures. During this entire period the patient received streptomycin drops through the medial canthus. It is interesting to note that the nasal portion of the ulcer healed first, the part proximal to the site of application of the streptomycin. Following 25 days of treatment the ulcer had completely healed, and the patient was discharged symptom-free. One month later the vision, with correction, was 6/15.

Case 9. B. W., a white woman aged 41 years, was admitted on October 9, 1945. For two years the patient had had recurrent inflammation of both eyes. Four weeks before her admission both eyes became acutely inflamed and sore. The right eye did not improve with treatment.

Vision was limited to perception of hand movements. The lids of the right eye were red and severely inflamed; there was some mucopurulent discharge. A staining ulcer involved the entire lower half of the cornea. There was also scarring, with some leukomas present. Slitlamp examination of the right eye showed marked haziness of the cornea throughout most of its circumference and especially in its central half. There was infiltration of the deep layers of the cornea, especially of the posterior half, with one large, dense area of infiltration involving the entire thickness of the cornea just below its crest.

Treatment. The right eye was treated with a 1-percent solution of atropine sulfate, 2 drops, three times a day; hot compresses for 20 minutes, four times a day; and 2 drops of streptomycin, every two hours day and night. On the second day the pain had gone. There was only slight staining. Slitlamp examination revealed healing at the margins of the ulcer with curling of the edges inward toward the cornea. Five days later, no ulceration was seen with the slitlamp, and no staining. The patient was discharged symptom-free eight days after the start of treatment with streptomycin. Vision on discharge was 1/60.

DISCUSSION

Although cultures were made from the ulcer margins, no bacteria grew, but cultures made from the inferior cul-de-sac showed *Staphylococcus albus* and occasional *Streptococcus hemolyticus*. The control group of 13 patients with corneal ulcer was hospitalized for an average of 20 days in comparison with an average of 15 days' hospitalization for nine patients treated with streptomycin. There were no patients in the control group whose condition was comparable to that in case 4 (corneal ulcer complicating exophthalmos), or in case 8 (neuroparalytic kera-

titis complicated by corneal ulcer). If these two cases are not considered in totaling the required days of treatment, the

* As these patients had tarsorrhaphies, it was impossible to determine the day the ulcers were healed.

treated group was under medication 12 days and the control group, 20 days. The

average duration of pain in the control group was four or five days, whereas in those treated with streptomycin, the pain was usually gone by the second day.

We were unable to determine any difference in the vision of patients whose ulcers were treated with streptomycin and of those used as controls.

It is our belief (table 1) that in the small series studied, the duration of pain was shortened, the healing of the ulcer was accelerated, and the total time of hospitalization was shortened.

CONCLUSION

Streptomycin, a nontoxic antibiotic substance derived from *Actinomyces griseus*, was found to be a useful adjuvant to the treatment of corneal ulcers with atropine sulfate, hot compresses, and typhoid vaccine.

LEGAL OPHTHALMOLOGY*

JOSEPH H. HINSHAW
Chicago

Every action brought into court by one person against another is based upon a duty which that one owes to the other, and failure to perform that duty. If it is a contract, the suit is on a breach of the contract. If it is a tort, it is a breach of a legal duty which the law imposes. To illustrate, when two men are driving automobiles, each owes the other a duty to exercise ordinary care. If one violates that duty to his neighbor, he has an action against the one who causes the injury. Likewise, every duty in the medical profession is based upon the same relationship. Every operation which a physician or surgeon performs is performed under a duty created by law. The law thus creates a duty on the part of every physician. The law says, in general, that it is the duty of every physician or surgeon to bring to the treatment of every case that degree of knowledge, skill, and care which a physician or surgeon in good practice would ordinarily bring to such a case in that community. That, of course, is a somewhat broad definition. In all cases, these words—knowledge, skill, and care—are used to define the duty.

A physician is not an insurer that he will make a cure. That is not part of the bargain. He is not even sure that he will improve the individual's condition. His duty is to bring to the case that degree of knowledge, skill, and care which physicians in good practice would bring. The difficulty arises in the matter of proof of knowledge or skill or care, or the lack of it; and proof of fulfillment of that duty, of course, is made before a jury. Under the constitution of our coun-

try, every person, if he chooses, has a right to trial by jury. The jury, under the laws, decides the facts. When we have a jury trial, the duties which are upon the Court are divided into two fields; the judge, decides the law, and the jury decides the facts. The jury is supposed to decide the facts, within the letter of the law, as the judge lays it down. The judge has no choice. The law is there before the case is tried, and he interprets it as he believes it to be.

In the last analysis, however, the jury decides the facts, including the question of whether or not the physician or surgeon has brought to the case that degree of knowledge, skill, and care which he should bring. It is quite obvious that most of the juries—probably all—know so little about the subject of a controversy between a patient and a physician as to be completely lost in the technicalities of the subject. Some questions are simple and some definitely not so simple. At any rate, we start out by proof first that a physician is licensed, which he has to be to give any treatment to any patient whether he charges for it or not. It is immaterial whether he makes a charge or not; his duty to his patient is exactly the same. Then he gives proof of his knowledge by showing the college where he spent so many years; that he interned at such a hospital, or practiced under someone recognized as a famous physician or surgeon; that since then he has had some special training; the nature and length of practice in a particular field; whether he is the author of any treatises or books on any subject. Proof of skill is made by proof of such facts

Proof of a physician's care, which is usually the cause of the controversy, is

* Read before the Chicago Ophthalmological Society, November 19, 1945.

made by proof of details of the particular operation or treatment that is the subject of controversy. Proof of lack of knowledge or lack of skill is not made by showing undesirable results, because the fact that there was an undesirable result, in itself, is no proof whatever that the treatment was not proper, nor that the result came from inadequate knowledge or failure to use proper care. Logically, the result, alone, proves nothing. The fact that the doctor made an improper diagnosis, which he may admit at the time of controversy was improper, or that, if he had to do it over he would do differently, does not mean lack of knowledge or skill or care. Proof of failure to furnish proper care is made only by proof of failure to do the things which a good physician, or a physician in good practice, would bring to such a case; and, therefore, the doctors hold the necessary proof in the palms of their hands. As a matter of fact, before there can be proof of failure in the duty of the doctor, there must first be proof by a qualified person who can say that proper treatment was thus and so, and that the doctor failed to follow such procedure, with a connecting link to show that his failure was the cause of the bad result that followed.

There are, of course, exceptions to that method of proof. The complainant's difficulty is that he cannot get one good doctor to testify against another—or against a bad one, so far as that is concerned—except in cases that are so flagrant that everyone realizes something has to be done. Part of this reluctance is due to timidity, part of it to fear that he may be in a similar situation some day, and part of it to a desire not to cause trouble to a fellow practitioner. As I said, there are exceptions to the rule of proof. You do not need the testimony of a physician or surgeon to prove that a doctor enucleated a good eye instead of a

bad one, or extracted a tooth that was sound instead of an aching one, or that he burned the patient with some diathermy instrument, heat lamp or something of that sort, which if properly operated would not cause such a result. There are some cases which hold that where the doctor himself operates an X-ray machine, and a bad result follows, the bad result itself is evidence of bad management or carelessness, because ordinarily these things do not happen. The thing speaks for itself. This principle first arose in connection with common carriers. If you buy a ticket and the train jumps the track, that is all the proof a passenger needs. It is up to the railroad company to show why the train is off the track. So this doctrine is made to apply to certain treatments. Some of these cases may be defended on the ground that an individual is subject to some idiosyncrasy, peculiar to him alone, such as a peculiarly sensitive skin, and the like. Not always will that be the case, because it may be the duty of the physician to find out, in advance, whether the patient suffers from some obvious idiosyncrasy. The doctrine of "the thing speaks for itself" has at times been used in cases where a sponge is left in the abdomen at operation. The fact that a sponge is left in the abdomen after operation does not, under most decisions, however, of itself create a liability. Under the law of most states, it is the duty of the nurse to count sponges, and, I think, the instruments that are used; and it is held good practice for the surgeon to rely upon the count of the nurse for sponges and instruments. He can show that he had the nurse count the sponges when he was ready to close the incision, and that she told him the count was correct. Most sponge cases are defended in that manner.

Suppose a case where an injury has been caused as a result of negligence. For

example, an elevator falls and someone has an injury, and he sues the elevator operator for that injury; and suppose, thereafter, some physician or surgeon is guilty of malpractice in his handling of the injury. The injured can file suit against the operator of the elevator and recover damages, and if the patient has exercised ordinary care in the selection of a surgeon, the operator of the elevator is liable to the person injured for the entire amount of damage, including that which resulted from poor medical practice; the reason being that the ultimate result was proximately caused by the fall of the elevator. The injured may, at the same time, file suit for malpractice and may recover from the surgeon the damage caused by malpractice. However, this is a point you might have occasion to use some time. In the event a settlement is made with the operator of the elevator, and the operator of the elevator takes a release from the injured person, the injured is deemed in law to have had a satisfaction of his cause of action, and the release taken by the elevator operator automatically releases the physician or surgeon from the charge of malpractice.

In connection with this same subject is the subject of hospitals, generally. You will have to deal with this from time to time, and we might as well cover it. Under this head, hospitals are placed in three general classifications. First, the ordinary hospital operated for profit—such a hospital, its staff, nurses, and attendants, are liable for torts on the same basis as any individual. Second, a hospital that is a charitable institution, referred to as an eleemosynary institution, not operated for profit. Under the law, a charitable hospital is not liable for its negligence or torts. Suit cannot be maintained against it for negligent acts of its staff or nurses or attendants. Its staff and nurses and attendants would be liable as would any

individuals. Under this head there have been some changes in the law.

Many of the old hospitals which had individual endowments had a very limited number of investments, but nowadays capital given to a charitable institution has to hunt around for a place to work. It is difficult to keep the money invested carefully, and at the same time make it earn anything. Chicago University is an eleemosynary institution, and it owns buildings around the city. If the neighborhood changes, all kinds of people become tenants in these buildings. Injuries occur and the University is sued. Some states divide the activities of charitable organizations into two categories. Some states excuse such an institution from liability for negligence so far as its activities are concerned with treatment of the individual. It is doing the very thing for which it was created. Yet, if such an institution is carrying on a separate business for the purpose of making money, such as renting buildings, even though the money is eventually spent for the purpose of charity, the institution is not excused from liability for negligence occurring in the course of carrying on the business, such as renting, wherein the institution earns the money.

There is a third class of hospitals, those which belong to the Government or State. One may not file a suit against the Government or State. It is true, we do have Courts of Claims, in which certain debts may be allowed, by the State, but in these Courts, a claimant does not prosecute his claim, as a right, but as a suppliant. There is no liability upon the State, nor upon any branch of the State, for negligence or torts committed in the course of governmental operations. The school board, for instance is not liable. One cannot sue the school board for whipping a child. The individuals working for these various governmental institutions are

liable in their own right personally. I remember a case wherein a patient had been sent to the X-ray room, and on the way back was simply rolled off the cart. He sustained a skull fracture and died. It was a charity hospital. The nurse had nothing, and that was the end of the case, because the hospital was not liable.

Nurses, like doctors, are duty bound to bring to the case they have in charge the same knowledge, skill, and care that nurses ordinarily bring to like cases. The only trouble is that many nurses step over their bounds. They become so accustomed to doing things that they try to do a few things extra, which doctors only should do, and get into trouble.

Hospital attendants are liable only for a failure to exercise ordinary care.

In connection with the field of expert testimony, all of you, sooner or later, will have some experience. As I said before, the facts of a case are determined by the jury. The jury has to decide first whether there is an injury, whether the fracture has healed in apposition, and so forth, or whether there was shortening, or other abnormal result. While the jury, in the last analysis, has to make a decision, the thing resolves itself frequently into a controversy between doctors. The doctor may not invade the province of the jury. The expert, the doctor, cannot tell a jury what caused the injury to happen, because the proximate cause or causal relationship between the accident and injury, or reasoning process which follows to a conclusion, is in the law a question of fact, which the jury must decide. So, we have the problem of getting the knowledge of the physician or surgeon to the jury in such form that it will enable the jury to know the facts without the doctor telling them what they have to do. We have a rule, therefore, that runs like this: Whenever, in any given field, proper conclusions can be arrived at only by a

person who has special knowledge in that field, the law allows expert testimony. That may apply to the engineering field, the electrical field, medicine, or any highly specialized field. Since the physician or surgeon may not invade the province of the jury and tell the jury what they ought to decide, we have a process of allowing the expert, in whatever field he may be, to state an opinion based upon a hypothetical set of facts as to what might or could happen. That process works in this manner: First, all the ordinary circumstances which may be supplied by a layman or the patient himself are put into evidence in ordinary terms. Then a physician or surgeon is called on behalf of the one making the claim, and he states such facts as do not deal with the opinion. Then the reasoning process is followed through by allowing the lawyer to state his hypothesis. For example, he says: "Assume, doctor, that a person who was on such a date well and hearty, had no broken bones, suffers a fall in an elevator and, thereafter, it was discovered that he had a spiral fracture of the femur between the hip and the knee; and after certain treatment it was found that the bones which were fractured are in the position indicated by certain X-ray studies interpreted here before you; do you have an opinion as to whether or not there might or could be a causal relation between the blow and the fracture as indicated by the X-ray film?"

The doctor is allowed to say what might or could happen: "In my opinion, there might or could be a causal relationship." He does not say: "There is a relationship in my opinion." He cannot say that. The judge would strike it out immediately, because that is what the jury must decide.

Remember, the questions will follow that pattern: "Do you have an opinion as to whether there might or could be a causal connection." If the doctor has an

opinion, the answer is not that it did, but that it might or could. The jury will decide whether actually it did. You may answer: "It might and it could."

This sort of anomaly in the law is qualified to a great extent by allowing the doctor, when he has stated his opinion that a certain result might or could happen, to give his reasons therefor. The doctor should be asked: "Doctor, will you state your reasons for that opinion?"

If the doctor is honest, his opinion is probably correct. The doctor on the other side may likewise give his reasons, and the jury has some logical ground for choosing between the two. If you are called upon to testify as an expert under these circumstances and the lawyer forgets to ask you for your reasons, remind him that you would like to state your reasons, because your opinion backed by reasons is worth 10 opinions with no reasons.

A hypothetical question could wander all over wide territory, but there are certain rules which govern them. A hypothetical question must come within the facts or evidence. If the evidence is not in dispute, it must incorporate all the facts. If there is any objection to the hypothetical question, the objection must say where it differs from the facts. The opinion of one doctor, for instance, is not accepted as a part of a hypothetical question.

There is also a limit to the opinion. The doctor may not speculate as to a conclusion so far as any permanent or future disability or limitation is concerned. The doctor who expresses an opinion as to what may happen must respond with a "reasonable degree of certainty," and unless he can, it is called speculation. He cannot say that it is possible that the patient might have hemorrhages or apoplexy, because it is all outside the "reasonable degree of certainty" which the law requires. Evidence which is in the realm of speculation cannot be admitted.

An attending physician may testify in answer to a specific question, as to a patient's subjective symptoms. If he has not treated the patient, he is limited in testimony purely to objective symptoms. Hearsay testimony is generally not admissible. A statement by a patient to his attending physician, however, is an exception to the rule and will be received as evidence. Anything the patient tells his physician concerning his physical condition is not hearsay. In many cases, controversy has arisen over what is and what is not a subjective symptom.

In connection with testimony by experts, the question of cross-examination comes in for a great deal of dispute. The lawyer may attempt to cross-examine on medical questions, sometimes with success and sometimes not. Ordinarily, cross-examination is limited to the subject matter of the questions asked on direct examination. Additional questions, however, may be asked, when directed to testing the doctor's memory or his qualifications in respect to the medical field in question. Under this head, a skillful lawyer can give a doctor a rather thorough examination.

Sometimes the question arises as to whether chiropractors can act as expert witnesses. They can if they show they have special training.

You may be interested in what is necessary to prove a doctor's bill. All the doctor has to do is to say that he knows what a fair charge is, and that the amount is a fair, reasonable, and customary charge for such services in the community in which he is practicing. This varies with communities, as you know.

I have had a good deal to do with expert witnesses in the medical field. You can take this advice or leave it. Doctors seem to have a feeling that their patient is theirs. They develop, in the course of treatment of a patient, a certain loyalty and love that it is almost impossible to

overcome. It is a good thing for the community that this is so, because the community gets the benefit of that love and care. Usually the doctor who does not have some of that feeling is not worth his salt as a doctor. From the standpoint of the Court and the lawyer, however, this causes trouble. When there is a controversy between a patient and another person, the doctor seems to feel that it is his moral duty to come to Court and fight that patient's battle. If the patient has a joint that is somewhat ankylosed, he is likely to say there will never be any improvement, when he knows it is not so. He feels morally justified; he is helping his patient maintain his side of the case. You may feel this is morally justified, but as a matter of fact it is the difference between right and wrong. If you come into Court and knowingly testify that a patient has more injury than he has or less than he has, you are just as guilty as if you blew a safe or stole the money out of a cash drawer. That may be hard to swallow, but it is your pill; I do not have to take it.

There is a long history connected with honesty. You may have read Breasted's "Dawn of Conscience." If you go back to prehistoric men, you will learn there was a time when man was not concerned with conscience at all. When he and his friend went into the forest, back to back, to fight wild animals or enemies, each defended the back of the other. That is how they lived, and loyalty to one another grew to be an ironclad law long before anybody thought about conscience. Consequently, loyalty to one's friends is still a trait in humanity so much stronger than honesty that people ordinarily honest, decent, and careful will tell a lie for their friends when they will not tell one for themselves. I can prove that to you. People of two different churches get into two automobiles to go home. They have a collision. The people in one car will defend that

car's driver, and likewise the other people will defend the other driver. The same is true of people riding in a street car. If there is an accident, they will defend the street car. It is loyalty to the crowd you are with. I do not blame you for that kind of view. It is natural. But, those of us who are supposed to have more moral education than others, and a greater discerning power along these lines, when called as expert witnesses, should sit down and think carefully what are the facts.

The testimony should then follow the truth, regardless of consequences.

We are also confronted with this situation: Frequently, a doctor comes into Court and has forgotten all about a particular case. When he is called upon to testify, he should take the time to check over the hospital records and the history sheet and refresh his memory. It is a nuisance, but it is his duty to do so. He picks up his notes, and the attorney objects to his reading notes. This is a legitimate objection. He is the witness, not the notes. If he does not now know what is in these notes, and if he knew at the time he wrote them, that they were correct, and that they are in the same condition as when written, the notes themselves may become evidence. He may be allowed to refresh his recollection from these notes or from the X-rays or a drawing or anything of the sort, or from anything which will, in fact, refresh his recollection. Thereafter, he may testify from his own memory, provided the thing used to refresh his recollection actually did refresh it. If he is lost without his notes, he should ask permission to review them, then put them down and tell the facts, not from the notes, but from his memory, so refreshed. I am sure all of you who call for this protection will get it.

I shall be happy to answer any questions anyone may have if I am able to do so.

DISCUSSION

DR. GUIBOR: We have considerable difficulty in getting nurses these days to aid in particular, cataract patients; are we allowed according to law to have a lay person watch that patient?

MR. HINSHAW: I think this is really a medical question rather than legal. It is the duty of a doctor to bring to his patient the care and knowledge which would ordinarily be brought to such a case by physicians in good practice. Emergencies are excusable. You may not be able to do what you would like, but your duty includes aftercare. If physicians in good practice do, as a rule, leave such cases in the care of a lay person, then in doing so you are in good practice. If they do not, you are not.

DR. SOPER: Why does the Court require the doctor to answer questions instead of allowing him to tell the facts in his own language?

MR. HINSHAW: If the lawyer who represents the side for whom you are testifying knows his business, you will not be confronted with that situation. The way to dispose of the difficulty with reference to complicated questions, is for the lawyer to break these questions up into simpler segments, and take one at a time. He can put them together when he argues with the jury. The doctor wanders out of legal bounds when he starts to talk about the medical side, without knowing the bounds.

DR. HOFFMAN: What about those questions which cannot be answered honestly "Yes" or "No"?

MR. HINSHAW: Always the witness has a right to object to giving any opinion, if, in fact, he has no opinion. He can say "I cannot answer a question Yes or No." If it cannot be answered Yes or No, usually he can say—"On that point I do not have

an opinion." . . . If you do not know what to do, you always have a right to turn to the Court and say "Do I have to answer it? May I answer it in my own way? Or may I give my reasons?" You will usually find that latitude will be allowed.

DR. MUNDT: I should like to know Mr. Hinshaw's opinion of the possibility and probability of putting over the Minnesota Plan. If we all stood there and saw an accident, there would be considerable divergence of opinion as to what we saw. It is difficult for a man who has had a patient under observation not to have arrived at a conclusion that he should do something for the patient. But, I think, at times, the lawyer falls down on calling a man as an expert witness without having had a discussion as to what was to be brought out. Men are frequently put on the witness stand without any idea as to what is being shown. In the industrial boards very frequently the file of the case is sent to you.

MR. HINSHAW: This Minnesota plan is the plan by which there is coöperation between the Bar Association and the Medical Society, for the purpose of eliminating, on both sides, testimony which is not true. The Medical Society has a committee appointed for the purpose of judging testimony which is claimed to be out of bounds. Whenever a lawyer believes such testimony has been given, he has a record made and submits it to the Medical Society. If the Committee of the Medical Society is of the opinion that the testimony does transcend the bounds of propriety or honesty, the doctor is called in for consultation and advised. If this is repeated, he may immediately be expelled. The same is true with the Bar Association; its members may be disbarred for similar actions.

GENERAL ANESTHESIA IN OPHTHALMIC SURGERY*

MORRIS BIEN, M.D.

New York

Except in the case of children, local anesthesia may be used for practically all ophthalmic surgery. Having made this reservation, I shall proceed to discuss this specialized subject, "General anesthesia in ophthalmic surgery" under the following four headings in order to present the salient points without too much overlapping and to integrate the whole subject matter. (1) Patients suitable for general anesthesia. (2) Operations suitable for general anesthesia. (3) Premedication. (4) Anesthetic agents.

Patients suitable for general anesthesia. That children are best operated upon when they are under general anesthesia is a fact commonly accepted by ophthalmic surgeons. A second type of patient for whom general anesthesia is indicated is one so apprehensive, so emotionally unbalanced, that although a local anesthetic would be adequate, the psychic trauma is sufficient to warrant general anesthesia. This type is encountered in general surgery and also requires general anesthesia when operated upon for cysts, varicose veins, and the like.

Operations suitable for general anesthesia. Although it is true that local anesthesia can be employed for practically all operations, nevertheless general anesthesia is indicated in a number of instances. This is so in cases requiring extensive plastic surgery, for the local anesthesia might wear off before the operation has been completed. Acute

glaucoma could also be included in this category, not only because the pathologic change involved makes local anesthesia less effective but also because the brevity of the operation favors the use of general anesthesia. Because of psychic factors, it would be well to include enucleations also.

Premedication. Since premedication determines the course of an anesthesia, a better understanding of this subject is essential. One may approach it by asking: what does premedication try to accomplish? First, it seeks to allay apprehension. Second, it is used to lower the threshold for pain so that a smaller quantity of the anesthetic will be required. Third, drugs are used for prophylactic measures. For example, atropine or scopolamine is used to counteract the action of pentothal. Fourth, it is necessary to dry up the secretions which obstruct breathing and cause postoperative nausea and vomiting.

The drugs that are used for premedication are the hypnotics (barbiturates); the opiates (morphine, dilaudid, pantopan, codeine, demerol); and the belladonna derivatives (atropine, scopolamine). A long-lasting barbiturate such as phenobarbital may be administered on the night before the operation; a combination of morphine and scopolamine (in the ratio of 1 to 25) one hour before the operation. This point about the use of an opiate should be remembered: Its action lasts from 3 to 4 hours, so that if the operation takes one-half to 1½ hours to perform, as it usually does, the analgesic properties take effect and lessen subsequent restlessness due to pain. However, if barbiturates are given preoperatively, the postoperative restlessness will be increased, unless

* From the Department of Anesthesiology, Mt. Sinai Hospital. Read before the New York Society for Clinical Ophthalmology, November 5, 1945.

an opiate is added, for the barbiturates are not analgesics. To draw a parallelism, when a barbiturate has been administered to an obstetric patient, restlessness will follow even though there is no awareness of pain because of the action of the hypnotics.

Both avertin and pentothal are used as basal anesthetics. I prefer pentothal for children and avertin for adults. The pentothal dose is computed on the basis of 1 mg. for each 50 lbs. of body weight. The total amount is dissolved in 30 c.c. of tap water at body temperature. It is administered rectally with a tube, slowly, while the patient lies on his left side.

Anesthetic agents. Ether is the best anesthetic agent for children. It has the widest margin of safety, and the various planes of anesthesia can be closely watched. Induction may be performed by means of ether, ethyl chloride, vinethene, or nitrous oxide. For maintenance of anesthesia, ether can be given by nasal catheter, by the use of an endotracheal tube (either through the mouth or the nose), or by means of an airway fitted with an adapter to which the tube is attached. When an endotracheal tube is employed, the anesthetist is completely out of the operative field, an adequate supply of oxygen is assured, and the anesthetist can easily control the patient.

Another widely used anesthetic is pentothal sodium. The virtues of this agent have been universally acclaimed. Much has been written of its wonderful properties—easy administration, smooth induction, minimal postoperative nausea or vomiting, and rapid recovery. Although pentothal is an effective agent, it is not the drug but the anesthetist who is responsible for good results. Proper administration is, after all, the factor that determines whether the patient has a

smooth induction, an even course during surgery, and minimal postoperative effects.

Pentothal has become an excellent addition to the armamentarium of the anesthetist. It was first used clinically in 1934 by Lundy at the Mayo Clinic. Since then, its composition has not been changed, but its administration has been modified to a considerable extent. At first, a 10-percent solution was advocated. Now a 2½-percent solution is usually administered. The question as to speed and quantity of administration has also been answered. When the drug was first used, a certain amount was given for a certain number of minutes, but the dosage was never to exceed a gram. Today, however, pentothal or any other agent is given according to the needs of the patient, not according to a formula on a bottle.

A brief review of the physical properties of pentothal shows that it is broken down rapidly in the body, presumably in the liver, but how or why is not known. We do know how other barbiturates are detoxified, but not the *modus operandi* in the case of pentothal. There is a rapid induction, but no one can determine the course of the anesthesia.

Some of the complications that can occur include: hiccup, jactitation, excessive secretion, depression of respiration, nausea, and vomiting.

The following routine is employed when pentothal is the anesthetic agent: An adequate dose of morphine and scopolamine (in the ratio of 1 to 25) is given one hour before the operation. After the patient has been brought to the operating room, placed on the table, and draped, anesthesia is started. It is recommended that a local anesthetic be used, whenever possible, after the patient is asleep and before surgery begins. By decreasing the amount of pentothal that is required, the risk is minimized.

In conclusion, the following general statements may be made: The anesthesiologist has two responsibilities—to the patient and to the surgeon. While he is selecting the best anesthetic agent and the procedure best suited to the patient, he must always bear in mind that the anesthetic risk can be equal to, or less, than

the surgical risk; but it can never be greater. The anesthetist makes the surgeon as comfortable as possible, gives him a clear field in which to work, and enables him to devote his entire attention to the operation.

HUNTER H. ROMAINE, M.D.

New York

Severe erythema exudativum multiforme is a disease of acute onset with fever, conjunctivitis, stomatitis, and cutaneous lesions. Its general course, although seldom fatal, is protracted, and its ocular sequelae often result in partial or total loss of vision. The etiology is obscure and pathologic findings are non-contributory.

Duke-Elder¹ lists only four cases of the purulent conjunctival form of erythema exudativum multiforme. Two of these cases were reported in 1922 by Stevens and Johnson² for whom this syndrome of the disease has been named.^{3,4} The other two cases referred to by Duke-Elder are those of Wheeler⁵ and Bailey.⁶ Further mention of this disease in the literature includes the cases of Rutherford,⁷ Ginandes,⁸ Givener and Ageloff,⁹ Rosenberg,¹⁰ Lever,¹¹ and Murphy.¹²

Throughout the literature on Stevens-Johnson's disease which we have con-

sulted, there was not mention of the relation of lacrimation to the corneal condition. Conversely, Bruce,¹³ in describing keratoconjunctivitis sicca, finds no associated skin lesions analogous to erythema exudativum multiforme. It seems, therefore, of interest to present the ocular complications of the later stages of this disease in association with deficient lacrimation and a resulting keratoconjunctivitis sicca.

CASE REPORT

T. D., an Irish-born woman aged 28 years, was admitted to the Willard Parker Hospital on April 28, 1944. The patient had been under treatment for nervous symptoms during the previous six to eight weeks, using tincture of belladonna, phenobarbital, and progynon-B. Prodromal symptoms typical of measles progressed to a state in which diffusely confluent, erythematous, maculopapular eruption enveloped the face, the neck, the trunk, and the extremities, in association with scattered, large, confluent, thin-

* Presented before the Section of Ophthalmology of the New York Academy of Medicine, on December 17, 1945.

Fig. 1 (Richards and Romaine). Poorly regrown fingernails, shown six months after the acute phase of the illness.

walled bullae filled with clear fluid. Bullae appeared also on the mucous membranes. The past history revealed that the patient had suffered from a migratory polyarthritides and had had an ovarian cyst removed.

On admission, the temperature was 103°F., and the patient was dehydrated and prostrated.

Desquamation followed the acute condition, involving skin and mucous mem-

Fig. 2 (Richards and Romaine). Both index fingernails are shown in a close-up view.

branes, resulting in edema, necrosis, and mucopurulent discharge. Even the fingernails were lost (figs. 1 and 2). Bloody urine with casts, tracheal obstruction, and conjunctival adhesions occurred. The general treatment included saline infusion, plasma and whole-blood transfusions, vitamins, and the administration of penicillin.

Ocular examination. The eyes showed destruction of the corneal epithelium and adhesions between the necrotic palpebral and bulbar conjunctiva. Treatment consisted of dilatation of the pupils with atropine, irrigations of the conjunctival sac with saline solution, and instillation of

Fig. 3 (Richards and Romaine). Contact lenses are shown without corneal segments.

cod-liver oil. To combat the adhesions, contact lenses without the corneal segments (fig. 3) were employed, as suggested by one of us (H. R.).

The general condition of the patient having improved, she was transferred to a ward of the New York Eye and Ear Infirmary on June 12, 1944, for a continuation of the ocular treatment. At this time, there was pronounced photophobia. The corneas stained faintly with fluorescein. In the cornea of the right eye a macula was observed lying inferiorly; in that of the left eye there was a central infiltration. After a week, the patient was discharged for treatment in the clinic, consisting of instillations of atropine and intermittent patching of the eyes. Prog-

ress was poor, and the opacification of the corneas increased, accompanied by superficial and deep vascularization, more in the right eye than in the left. By the end of three or four weeks, a number of superficial ulcers that had developed became covered with epithelium. The corneas showed a finely stippled staining with fluorescein, visible only with the slit-lamp. Vision was reduced to 5/200 in the right eye and 20/200 in the left.

On August 4, 1944, a peritomy on the right eye was performed with an electrocautery, resulting in an immediate decrease in the vascularization and opacification, and an improvement in the vision to 20/200. The vascularization returned soon, and since the infiltration increased simultaneously, X-ray treatment was undertaken by Dr. Thomas Graham, using 75 r each week to each cornea up to a total of 900 r.¹⁴ After five doses, vascularization and infiltration were apparently reduced, but vision had decreased to 1/200 in the right eye and 5/200 in the left. Each cornea showed a finely stippled staining with fluorescein.

The patient was readmitted to the hospital on September 18, 1944, for treatment with irrigations of a solution containing 100 units of penicillin per c. c. of normal saline. This was done hourly, except during sleeping hours. The cornea of the right eye cleared considerably, that of the left slightly, and the photophobia decreased. Vision was 20/200 in the right eye and 20/70 in the left eye. After discharge, the patient's condition fluctuated between improvement and regression, with a gradual change from inflammation to healing with cicatrization. This paralleled changes in mucous membranes elsewhere in the body. Along with this change, typical signs of keratoconjunctivitis sicca appeared. The corneal epithelium maintained its stippled staining and dull-luster appearance. The

Schirmer test¹⁵ showed little or no lacrimal secretion. Routine laboratory tests were uninformative.

Local and general measures were employed in an attempt to relieve the photophobia and pain, and to prevent further ulceration, inflammation, and infiltration of the corneas, as well as desquamation of the conjunctiva from the lack of tears. The local measures employed were bland lubricants, holocaine and butyn ointments, atropine solution, dark glasses, and X-ray treatments to decrease neovascularization and to reduce infiltration. Frequent irrigations of the eyes with penicillin in saline solution were made. The general measures employed were vitamin therapy, including vitamins A, B₁, and B₂ in large oral doses for six months; pilocarpine with ammonium chloride for four weeks to stimulate secretions, progynon-B three times weekly for 10 weeks, and thyroid extract for four weeks.

The onset of manifest cicatrization was gradual, overlapping with the signs of inflammation, but exudation had definitely disappeared by the time that cicatrization signs had become apparent. Posterior symblephara, one infero-nasally in the right eye, and one supero-nasally in the left eye, occurred associated with a moderate obliteration of the fornices (figs. 4 and 5).

On November 15, 1945, a year and a half after the onset of the illness, vision was light perception in the right eye and 20/200 in the left eye. The Schirmer test showed a greatly reduced lacrimation. In the left eye superficial vascularization had increased, and the corneal epithelium still showed a finely stippled fluorescein staining, with no filaments. In the right eye, however, the cornea had undergone recurrent episodes of ulceration, until on November 10, 1945, an ulcer perforated with incarceration of the iris. On November 17, 1945, the right

Fig. 4 (Richards and Romaine). This right-eye photograph was taken six months following the onset of the illness, and shows: a, the area of early infero-nasal posterior symblepharon formation; b, the desquamated mucocutaneous junction of the lower lid; c, the injected conjunctival vessels; and d, the hazy limbus corneae inferiorly.

Fig. 5 (Richards and Romaine). The left eye shows a posterior symblepharon supero-nasally.

eye was enucleated at the New York Hospital (figs. 6 and 7).

Microscopic examination of sections of this enucleated globe, including the area of perforation, revealed a nonspecific, chronic, superficial inflammation of the cornea.

COMMENT

The findings in this case are consistent with those in Stevens-Johnson's disease, which is the purulent conjunctival form of erythema exudativum multiforme. Ac-

cording to Rosenberg,¹⁶ "differentiation of this disease at various of its phases must be made from septicemia, agranulocytosis, pemphigus, hemorrhagic measles, small-pox, Vincent's angina, and syphilis." This same author feels that "the differentiation is either apparent or readily determined or becomes manifest as the illness progresses."

The differentiation of severe erythema exudativum multiforme from acute pemphigus is difficult. Most patients with acute pemphigus do not survive. In those that do survive, the disease pursues a chronic course, and the final picture is similar to that of Stevens-Johnson's disease. In the acute stage, a Pels-Macht test¹⁷ may be used to differentiate this disease from pemphigus. In our case, it was not done. Cicatrization of the sub-

Fig. 6 (Richards and Romaine). This post-operative view of both eyes shows the empty socket of the right eye.

Fig. 7 (Richards and Romaine). The left eye in a close-up view shows a paracentral nebula, superficial corneal vascularization, and a poorly demarcated mucocutaneous junction of the lower lid.

conjunctival tissue with the formation of symblepharon and with obstruction of lacrimation is a finding common to both diseases, leading to keratoconjunctivitis sicca.

The main clinical points of differentiation of the present case of erythema exudativum multiforme from pemphigus are:

History. Ovarian dysfunction. Suspected allergy to belladonna and barbiturates.

Rash. Bullae with a surrounding erythematous halo. Symmetrical predilection for the dorsal surfaces of the hands and feet. Absence of successive crops of bullae.

Eyes. Chronic progressive course of the keratoconjunctivitis with predominance of corneal over conjunctival lesions.

SUMMARY

A case of the purulent conjunctival form of erythema exudativum multiforme (Stevens-Johnson's disease) is presented. The association of keratoconjunctivitis sicca with this disease is noted. Differentiation is made from pemphigus. Emphasis is placed on the dire ocular sequelae, with the loss of one eye and with reduction of vision in the fellow eye.

A COMPARATIVE STUDY OF SUTURES EMPLOYED IN SURGERY OF THE EXTRAOCULAR MUSCLES*

CONRAD BERENS, M.D., AND HUNTER H. ROMAINE, M.D.

New York

In an effort to evaluate the relative merits and disadvantages of the various sutures used in surgery of the extraocular muscles and to understand more fully the results obtained clinically, experiments have been performed on the muscles of rabbits' eyes and on other tissues.

In selecting sutures, size and weight rather than tensile strength have been used as criteria. When possible, sutures equipped with atraumatic needles have been utilized. In order to obtain results as comparable as possible, we have employed sutures manufactured by one dispensing house.[†] In evaluating results, we have studied the advantages, disadvantages, and the qualities of each suture, using several criteria.

The absorbable sutures used in these experiments were chromic catgut 3-0 (#1669), chromic catgut 5-0 (#1669D), and plain catgut 3-0 (#1667). The non-absorbable sutures were black braided silk 6-0 (#P242), white braided silk 6-0 (#P290), black twisted silk 6-0 (#1661), black braided silk 8-0 (#P277), twisted white cotton 3-0 (#1641), twisted white cotton 4-0 (#1273, special), Nylon 6-0 (#P336), and kaldermic plastic 8-0.[‡]

*From the Department of Research, New York Eye and Ear Infirmary and Department of Ophthalmology, Columbia University. Presented at the eighty-first annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, November, 1945. Aided by a grant from The Ophthalmological Foundation, Inc.

†The authors are grateful to Davis & Geck, Inc., Brooklyn, New York, for supplying the sutures used in these experiments.

‡Basic materials for manufacture are unobtainable at the present time as they are imported.

TECHNICAL FACTORS

The qualities considered in evaluating the sutures were: (1) ease of handling, (2) adsorption and absorption, (3) tensile strength, and (4) friction coefficient.

Ease of handling. There is no question that the nonabsorbable sutures are easier to handle than the absorbable, with the exception of nylon, which is by far the most difficult in the transparent small-sized material we have used. When the absorbable sutures have been prepared by soaking before use, the difficulty is somewhat overcome; but as soon as the sutures dry, the difficulty once more prevails.

In the case of nylon sutures, the material cannot be well softened, even on prolonged soaking. Because of this factor the sutures are difficult to grasp during procedure and are inclined to twist on themselves and cause considerable annoyance in the tying of knots. If the sutures are colorless, the technical difficulties are further increased because the fine sutures are exceedingly difficult to see.

The advantage of the braided over the unbraided suture is that there is less likelihood of broken fragments of suture material being left in the tissues after removal. On the other hand, the braided sutures are hard to pull through muscle tissue, Tenon's capsule, and even conjunctiva.

Adsorption and Absorption. The factor of adsorption is more important in the absorbable sutures than in the nonabsorbable. The ability of the suture material to absorb fluid weakens the suture in proportion to the amount of fluid ab-

sorbed; therefore, the greater the absorption the weaker the suture becomes. The nylon suture, as stated above, has practically no adsorption and thus retains its original state, even in the presence of fluids.

The nonabsorbable sutures absorb a small amount of fluid, but this does not affect their strength over a short period of time.

The absorption factor or the ability of the tissues to break down, destroy, or digest the suture material is, of course, most pronounced in the absorbable sutures. The rate of absorption by the tissue may be controlled somewhat by treatment of the sutures during their manufacture. Similar conclusions were reached in the study of sutures used in corneal and scleral tissue.¹

Whereas silk and cotton sutures are broken down following the process occurring at the site of the suture implant, the condition of the nylon sutures remains unchanged.

*Tensile strength.*² The third factor, tensile strength,* is one that may vary even in a small lot of sutures. The original tensile strength, provided it is at all adequate, is sufficient in any case to handle the stress placed upon it in muscle surgery and, therefore, the other factors involved are more important in the final outcome than is the original tensile strength of each suture.

Figures on the strength of the sutures used in our experiments were obtained by finding the tensile strength of a large number of sutures and recording the mean strength (table 1).

Friction coefficient. Nylon and chromic and plain catgut sutures have the dis-

advantages of possessing a poor coefficient of friction. The surfaces of all these sutures are smooth, do not readily produce friction against themselves when knotted, and, therefore, may prevent firm apposition of wound edges. Even when satisfactory surgical knots have been employed, it is not unusual to see slipping in this type of suture. In this characteristic the cotton and silk sutures have a definite advantage because a well-tied

TABLE 1
TENSILE STRENGTH OF SUTURES

Suture Material	Size	Tensile Strength in Pounds	
		Minimum	Maximum
Chromic catgut (#1669)	3-0	3	4
Chromic catgut (#1669D)	5-0	1	2
Plain catgut (#1667)	3-0	$\frac{1}{2} \pm \frac{1}{4}$	$1\frac{1}{2} \pm \frac{1}{4}$
Black braided silk (#P242)	6-0	1	$1\frac{1}{2}$
White braided silk (#P290)	6-0	1	$1\frac{1}{2}$
Black twisted silk (#1661)	6-0	1	$1\frac{1}{2}$
Black, braided silk (#P277)	8-0	$\frac{1}{2}$	$\frac{3}{4}$
Twisted white cotton (#1641)	3-0	2	3
Twisted white cotton (#1273, special)	4-0	1	$1\frac{1}{2}$

knot shows no tendency to slip and even a poorly tied knot has a better chance of producing satisfactory results. Furthermore, the resulting knot when tied with one of the first group is often two or three times as large as that tied with the latter group. A large knot causes mechanical irritation.

EXPERIMENTAL PROCEDURE

Extraocular surgery employed in these experiments was limited to recession with scleral fixation (retroplacement) and re-

* The Scott single-strand tester was used to obtain a mean average of tensile strength in the sutures used.

TABLE 2
RESULTS OF EXPERIMENTAL STUDIES OF SUTURES

Type of Operation	Number of Rabbits' Eyes	Sutures Used	Number of Days <i>in Situ</i>	Macroscopic State*	Microscopic State	Miscellaneous Factors
Suture implant	10	Silk (8 braided 6-0; 2 twisted 6-0)	10 days	Mild reaction	Leukocytic infiltration; few fibroblastic cells	No slipping of knot noted
	10	Cotton (3-0 and 4-0)	10 days	Mild reaction	Leukocytic infiltration; few fibroblastic cells	No slipping of knot noted
	10	Nylon (6-0)	10 days	No reaction	Fibroblastic infiltration; very few leukocytes	Slipping of knot noted in two cases
	10	Plain catgut (3-0)	10 days	Marked reaction	Massive leukocytic infiltration. No evidence of fibroblastic invasion	Slipping of knot noted in one case. Surgical knot untied in one case
	10	Chromic catgut (3-0 and 5-0)	10 days	Severe reaction	Massive leukocytic infiltration with occasional areas of necrotic tissue. No bacteria seen	No evidence of slipping of knot
Recession with scleral fixation and resection	5	Silk (4 braided 6-0; 1 twisted 6-0)	20 days	No reaction	Fibroblastic wall around suture. Occasionally lymphocyte	Sutures out in some cases†
	5	Cotton (3-0 and 4-0)	20 days	No reaction	Fibroblastic wall around suture. Occasionally lymphocyte	In one animal respiratory infection resulted in intra-ocular infection
	5	Nylon (6-0)	20 days	No reaction	Fibrous wall	
	5	Plain catgut (3-0)	20 days	Mild reaction	Leukocytic and fibroblastic infiltration with destruction of almost all suture material	Slipping of knot noted in three cases
	5	Chromic catgut (3-0 and 5-0)	20 days	Moderate reaction	Leukocytic and fibroblastic infiltration rather marked. Suture material not all absorbed	Slipping of knot noted in two cases
	5	Silk (4 braided 6-0; 1 twisted 6-0)	40 days	No reaction	Fibrous tissue replacement of suture**	
	5	Cotton (3-0 and 4-0)	40 days	No reaction	Fibrous tissue replacement of suture	
	5	Nylon (6-0)	40 days	No reaction	Fibrous tissue replacement of suture	
	5	Plain catgut (3-0)	40 days	No reaction	Very faint area of fibrous tissue replacement	
	5	Chromic catgut (3-0 and 5-0)	40 days	Mild reaction	Fibroblastic infiltration with scattered lymphocytic infiltration	
	5	Silk (4 braided 6-0; 1 twisted 6-0)	60 days	No reaction	Fibrous tissue	No evidence of sutures noted‡
	5	Cotton (3-0 and 4-0)	60 days	No reaction	Fibrous tissue	No evidence of sutures noted
	5	Nylon (6-0)	60 days	No reaction	Fibrous tissue around suture	No evidence of sutures noted. Evidence of irritation of overlying conjunctiva from points of the suture material
	5	Plain catgut (3-0)	60 days	No reaction	Fibrous tissue	

TABLE 2—(continued)
RESULTS OF EXPERIMENTAL STUDIES OF SUTURES

Type of Operation	Number of Rabbits' Eyes	Sutures Used	Number of Days in Situ	Macroscopic State*	Microscopic State	Miscellaneous Factors
Implant into skin, striated muscle of leg, heart muscle, and peritoneum of rabbits	5	Chromic catgut (3-0 and 5-0)	60 days	No reaction	Active fibroblastic infiltration	
	1	Silk (twisted 6-0)	30 days	Severe reaction	Necrosis. Strands of silk noted in fistulous tract. Bacteria seen	
	1	Chromic catgut (3-0 and 5-0)	20 days	Severe reaction	Large area involving muscles, conjunctiva and episcleral tissue, showing necrosis of tissue	No suture material found
	1	Plain catgut (3-0)	10 days	Severe reaction	Entire area necrotic	Infection involving entire periorbital tissue at time of enucleation
Implant into skin, striated muscle of leg, heart muscle, and peritoneum of rabbits		Nylon (6-0)		No irritation from sutures noted in specimens examined		

* Key to reactions: (1) Mild reaction—infiltration of small number of leukocytes and round cells, little or no edema, no marked changes in surrounding cells; (2) Moderate reaction—increased number of leukocytes and round cells, edema of the surrounding tissues with swelling and destruction of the surrounding tissue cells; (3) Marked reaction—an increase in the foregoing reaction with process reaching state of necrosis; (4) Severe reaction—large area of necrotic tissue to the extent of producing a slough.

† The sutures were either expelled by the tissue or removed in sectioning.

** Suture material absorbed or extruded and replaced by fibrous tissue.

‡ When microscopic sections were made, the suture material was apparently torn from the wound.

section operations. Sutures were also inserted into skin, striate muscle of leg, heart muscle, and peritoneum. In these experiments, cases in which infection developed postoperatively were not discarded, because we believed that it was of value to study the reactions of the sutures and the manifestations of infection. The eyes in the first group of cases were operated on by implanting the sutures without severing the muscle from its normal position, and the results were studied at the intervals shown in table 2.

Since there is a considerable variation in the size of the rectus muscles of the rabbit, the sutures were used alternately on different muscles. The superior and inferior recti were found more adaptable for experimental sutures. The oblique muscles, however, were used in many cases.

In all cases double-armed sutures were employed, and the clinical methods of recession with scleral fixation and re-

section were carried out. All sutures were tied with a primary double surgical knot followed by a square knot.

MICROSCOPIC AND MACROSCOPIC STUDY

The cases were followed and clinical evidence of reaction was observed over a varying period of time up to 60 days, and the eyes of several animals from each group were selected for macroscopic and microscopic study. The rabbit tissues studied microscopically* were examined

* The following method was used in preparing the microscopic sections: (1) Fix tissue in 10-percent formalin. (2) Place it in 50-percent alcohol for 24 hours. (3) Place it in 60-percent alcohol for 24 hours. (4) Place it in 70-percent alcohol for 24 hours. (5) Place it in 80-percent alcohol for 24 hours. (6) Place it in 95-percent alcohol for 24 hours. (7) Place it in absolute alcohol for 24 hours. (8) Place it in ether alcohol for 24 hours. (9) Place it in 1-percent celloidin (parlodion) for 6 to 8 days. (10) Place it in 8-percent celloidin (parlodion) for 6 to 8 days. (11) Place it in 15-percent celloidin (parlodion) for 6 to 8 days. (12) Place tissue in 15-percent celloidin in small jar or paper box under bell jar with

at the end of 10, 20, 40, and 60 days. A tremendous amount of work has been carried out in relation to the reaction and absorption of sutures in other tissues.³⁻⁷ Therefore, the relation of these factors in eye surgery to surgery in other parts

invasion of fibroblasts in the late stage, and the variations in these findings at different stages.

RESULTS

The type of reaction, rate of absorp-

Fig. 1 (Berens and Romaine). Chromic - catgut - sutures area (10 days). * A, Area in cornea where chromic catgut was placed. B, Note marked vascular and round-cell reaction in the stroma of the cornea.

of the body was studied on a minor scale. Sutures of the same type used in the eyes were inserted in skin, striate muscle of leg, heart muscle, and peritoneum. The absorption of sutures and subsidence of reaction were more rapid in the eye than in other tissues of the body. The difference in rate, however, was so slight that it was believed to be of little significance. The method of interpreting the foreign-body reaction produced in the tissues was by estimating the size of surrounding infiltration, the presence of necrotic material in and around the sutured area, the

tion, and final state of the tissues in which the sutures were buried are shown in table 2. From this table it is evident that in every case, in the early stages, there was marked reaction in and around the absorbable sutures. In many cases the reaction surrounding the chromic catgut sutures was so great that it simulated conditions found in the presence of infection (fig. 1). The possibility that this was an allergic type of reaction was investigated by Pickrell,⁸ and it was definitely believed to be a foreign-body reaction rather than an atopic manifestation.

The reaction surrounding plain catgut sutures was less marked but was definitely greater than that when nonabsorb-

chloroform for from 24 to 48 hours until it is hard. (13) Trim extra celloidin off around the tissue. (14) Mount on a block and place it in 80-percent alcohol. (15) Cut sections with the microtome (only the area where the sutures were placed). (16) Stain sections with hematoxylin and eosin and mount them on slides with Canada balsam.

* Corneal tissue is used to illustrate the reaction to the different sutures because the degree of reaction is demonstrated more clearly than in the muscle tissue.

Fig. 2 (Berens and Romaine). Plain catgut-suture area (10 days). A, Area in stroma of cornea where plain-catgut suture was placed. B, Note mild reaction in the stroma.

able sutures were employed (fig. 2). This area of reaction was reduced at later stages, and there was practically no evidence of reaction at the end of 60 days in the chromic catgut sutures and at the end of 40 days in the plain catgut sutures. The suture material, itself, was usually

absorbed within 30 and 20 days, respectively.

In the case of the nonabsorbable sutures, on the other hand, the immediate reaction was far less severe, the minimal amount being seen invariably in the nylon sutures (fig. 3). Little difference was

Fig. 3 (Berens and Romaine). Nylon-suture area in cornea (10 days). A, Where nylon-suture material was placed in stroma of the cornea. B, Note absence of reaction in the stroma and epithelium.

found in the reaction to cotton and to silk sutures, although in our opinion it was slightly greater in the case of silk than in that of cotton⁹ (fig. 4). The studies at the later stages showed that the non-absorbable sutures were surrounded by a wall of connective tissue. In the pres-

this fact, because the criteria were not cultured before their insertion.

CLINICAL USE OF SUTURES

Double-armed (6-0), colorless, nylon sutures have been used by one of us (C. B.) in 59 muscle operations (table

Fig. 4 (Berens and Romaine). Silk-suture area (10 days). A, Disintegrating silk fibers in area of implanted suture. B, Tissue reaction in the surrounding area.

ence of infection, reaction was severe in all cases. This reaction was far more pronounced if the sutures were of chromic or plain catgut, and apparently less severe if of cotton than of silk. Although the plain catgut sutures are supposed to become absorbed in three days (more rapidly in the presence of infection), we found particles of suture material in the tissues after as long as 20 days.

Infection in rabbits' eyes is difficult to avoid. In drawing conclusions we have included no cases in which severe infection occurred. The relationship of the type of suture to infection is not revealed statistically, although we noted more evidence of infection when absorbable sutures were used. We do not believe, however, that this can be attributed to the sutures, but we have no bacteriologic proof of

3). The reaction has been negligible in recession with scleral fixation (retroplacement) and resection of the medial, superior, and inferior recti; but when used in lateral-rectus surgery, the ends of the sutures, unless cut unusually short, tend to elevate the conjunctiva or project through it and maintain a mild reaction until the ends are cut shorter or removed. The sutures have been found especially useful in performing retroplacement of the inferior oblique, and 35 operations have now been performed with no apparent reaction and no infection. Fine curved needles are useful in this procedure, and, because of the proximity to the macula, reaction is to be avoided. Nylon has been found far superior to chromic catgut in transplanting Tenon's capsule,¹⁰ where chromic catgut seemed to be responsible for a severe

tenonitis and a failure in one patient.

Analysis of the postoperative complications in 179 patients (117 private patients and 62 clinic patients [table 3]) revealed that severe reaction to nonabsorbable sutures is frequently the result of retained suture fragments. The criteria for recording the presence of infection were the results of cultures taken at the time of the complications. Infection oc-

The absorption of sutures and subsidence of reaction was more rapid in the eye than in other tissues of the body.

Since it was our purpose merely to point out the advantages and disadvantages of the sutures used clinically and experimentally, we have not designated one suture as better than another but merely indicated the results obtained.

1. Cotton and silk sutures are the su-

Silk (of some form)	0	3	4	2	34	43
Chromic catgut	0	2	12	1	14	29
Plain catgut	0	2	5	1	40	48
Nylon	2	2	3	2	50	59
Total	2	9	24	6	138	179

* Of the 179 patients, 117 were private patients and 62 were clinic patients. Of the 9 cases in which infection occurred only three were recorded in private patients.

curred in only three operations on private patients. Of 62 clinic patients, infection occurred following 6 operations. We do not believe that the type of suture material is a major factor in the production of postoperative infection but, rather, that the major factor is contamination from some other source.

SUMMARY AND CONCLUSIONS

This comparative study of sutures employed in surgery of the extraocular muscles includes a discussion of technical factors (ease of handling, adsorption and absorption, tensile strength, and friction coefficient).

Extraocular surgery employed in these experiments was limited to recession with scleral fixation (retroplacement) and resection operations. Sutures were also inserted into the skin, striate muscle of leg, heart muscle, and peritoneum.

tures of choice when considered in the light of ease of handling, the braided sutures being preferable to the twisted type. Nylon (6-0) was found most difficult to handle.

2. From the standpoint of tissue reaction and tensile strength, the nylon suture (6-0) is the first choice and has been found most satisfactory clinically in surgery of the extraocular muscles. Fifty-nine operations have been performed. An annoying complication has been the irritation of the overlying conjunctiva by the stiff ends of the suture in operations on the lateral recti in two patients.

3. Of the absorbable sutures the advantage lies in the fact that sutures do not have to be removed, and the plain catgut produces far less reaction than does the chromic variety.

4. In the presence of infection, nylon,

cotton, and silk sutures are preferable to catgut, and chromic catgut is to be preferred to plain catgut. Experimentally, there was no marked relationship between the type of suture and infection. In those cases in which infection did develop, the greatest destruction of tissue was showed

by the absorbable sutures.

5. Both clinically and experimentally, plain-catgut sutures (3-0) are sufficiently strong permanently to attach any extra-ocular muscle under ideal conditions.

INFECTIONS AND REFLEX DISORDERS OF THE EYE FROM DENTAL AFFECTIONS*

DANIEL KRAVITZ, M.D.
Brooklyn, New York

Since 1940, when I¹ wrote on a similar topic, a number of papers on this subject have appeared in the literature. One of the most critical of these, by Woods,² was on the larger aspect of focal infection in diseases of the eye. These papers have caused me to reexamine critically the question of the relationship of ocular disorders to dental affections. A search of the literature on this subject reveals many contradictory statements.

BACTERIOLOGY

Rosenow³ was the first to show the widespread prevalence of the streptococci, and demonstrated how by passage through animals and media, the virulence of the germs could be made to vary. In other experiments, he proved the selective activity of the various strains of streptococci; that is, germs from foci of infection in patients suffering from uveal disease caused similar eye infections when injected into laboratory animals.

Billings⁴ became an early enthusiast for Rosenow's theories and he, more than anyone else, was responsible for popularizing and making these theories acceptable to the medical profession. According to him, a focus may remain dormant for years, because the natural defenses of the body prevent general infection; nevertheless, an insidious, slow, systemic intoxication may occur from this focal point of infection. At any time that the defenses of the body become diminished by overwork, dissipation, or exposure to cold or to trauma the latent focus may become activated. That a latent focus

may remain dormant for many years I have shown in another paper.⁵

De Schweinitz⁶ further broadened the idea when he defined a focal point of infection to be not merely an entrance for bacteria but also a place where conditions favor their acquiring the properties which give them a wide range of affinities for various structures.

Haden⁷ made apical cultures from 1,500 incisors, cuspid, and bicuspid teeth. In cultures from 400 vital teeth, only 15 percent were positive; but cultures from 600 pulpless teeth with negative X-ray findings were positive in 55.7 percent, and from 500 pulpless teeth with positive X-ray findings, they were positive in 72.4 percent. Nonhemolytic streptococci were by far the most frequent organisms found.

Chojnacki⁸ studied bacteriologically the devitalized teeth in 10 patients with iritis and in four patients with retrobulbar neuritis by injecting the infected material intravenously into rabbits. In most of the cases in which the eyes of the rabbits were involved, extraction of the teeth favorably affected the eyes of the patients. He concluded that negative X-ray findings did not rule out the possibility of apical infections.

Anastassoff⁹ found that four of six cases of iridocyclitis were of dental origin. Injecting the material from the teeth into laboratory animals produced iridocyclitis and immature cataracts in these animals.

Siniscal,¹⁰ after very careful and extensive experimental work, came to some very interesting conclusions. He found that injecting bacterial toxins from dental foci in man into albino rabbits produced

* Read before the New York Society for Clinical Ophthalmology, February 4, 1946.

no iritis; however, when he injected the bacterial organisms, iritis did develop in many cases. When he injected bacteria from the dental foci in patients who had concomitant iritis, iritis was more readily produced in the rabbits; but in rabbits which had had previous injections of bacterial toxins, the administration of bacteria produced iritis in a far greater percentage. It would, therefore, seem that the toxins diffusing into the blood stream over a period of months or years might sensitize the uveal tissue so that, later, bacterial emboli might more readily attack the tissue.

Many excellent observers have, however, come to exactly opposite conclusions.

Giani¹¹ injected many kinds of bacteria intravenously into experimental animals and found that the highest percentage of ocular involvement was produced by *B. prodigiosus*, and a very low incidence by the various strains of streptococci.

Cusumano¹² passed streptococci and staphylococci from eye to eye in a series of rabbits and later injected the germs intravenously. He found no elective affinity of the germs for the eyes.

Reiman and Hovens¹³ not only denied that the teeth could act as reservoirs of infection for other parts of the body, but they were unable, by inoculation experiments, to substantiate Rosenow's theories of elective localization.

Guyton and Woods¹⁴ after a recent survey, contrasted their conclusions with those from a survey made in 1941. They noted that the percentage ascribed to focal infection had decreased from 26.1 percent to 6 percent, and stated that this decrease paralleled their growing disbelief in the importance of focal infection as a cause of uveal disease. Brucellosis rose from a relatively unknown entity to 7.5 percent, while tuberculosis ranked

very high, 49.7 percent in the first, and 41.0 percent in the present survey.

A significant statement, susceptible to varying interpretations, was that their consultants were unwilling to lay stress on trivial and minor foci of infection, with the result that the percentage of cases of undetermined origin rose from 1.8 in the first survey to 11.0 in the last.

Schmidt¹⁵ also concluded from a study of 39 cases that chronic inflammation of the dental roots has no influence on the eyes.

REPORTS OF CLINICAL OBSERVATIONS

The average practicing ophthalmologist has been far from skeptical in relating foci of infection, particularly in teeth, to eye disorders. Indeed, Woods, one of the severest critics of the focal-infection theory, stated that: "The mass of clinical evidence is so formidable that it is difficult to dismiss it lightly on the sole grounds that it is only suggestive evidence."

The popular connection between the eye and the teeth goes back to antiquity. Wilmer,¹⁶ in an excellent historical review, reproduced a painting from the dawn of the Christian era showing St. Lucia, the patroness of sight, and St. Apollonia, the patroness of teeth, grouped together in one painting. This close connection has long been associated by the laity with the popularly known "eye tooth."

Cahn¹⁷ records that over 200 years ago, Fabricius Hildanus reported the loss of an eye from a dental abscess, and Richter,^{17a} in 1795, reported the case of a woman who was blind for several years, and then regained her sight after the extraction of a tooth.

Black¹⁸ divided the ocular lesions from dental disorders into two groups: (1) inflammation of the various tissues of the eye; (2) reflex irritations which pre-

sented themselves as sensory, vasomotor, or muscular disorders.

Moczar¹⁹ performed autopsies in 24 cases in which severe ocular complications had resulted from dental infections. He found that in the majority of cases there was a direct extension of the infection through the venous passages and, in 10 percent, the ocular infections were septicemic in origin. In other cases, ocular complications resulted from involvement of the contiguous bones or through the lymphatics.

Defong²⁰ reported two cases of orbital abscess in infants four and five months old, respectively, which were extensions from alveolar abscesses and osteomyelitis of the maxillary bones.

Wilmer¹⁶ reported several cases of uveitis that were cured when the involved teeth were extracted. There were no recurrences in any of his cases in over 10 years of follow up.

Steinbugler,²¹ in a survey of 53 cases followed for over a period of two years, found that infected teeth could cause practically any type of eye infection. There were 32 cases of uveitis, 4 of detached retina, 4 of episcleritis, 1 of retrobulbar neuritis, and other miscellaneous eye involvements.

Kieive and Reh²² reported a case of a hole in the macula in a woman, 37 years of age. Some vision returned after removal of the infected teeth. Smith²³ reported the case of a man with greatly reduced vision which cleared seven weeks after removal of two infected upper bicuspids.

Lagrange and Marq²⁴ reported a case of intractable iritis which cleared only after the infected teeth were removed. They stressed the importance of the teeth as a source of infection.

Boros²⁵ reported the case of a woman, aged 42 years, with a hemorrhage on the disc and stellate white spots in the macula

of the right eye. The greatly reduced vision returned to normal after the removal of 10 bad teeth. Kapuscinski (cited by Wilmer¹⁶) reported 51 cases of iridocyclitis which healed after extraction of the diseased teeth.

Prangen²⁶ emphasized the close relation between poor accommodation and dental disease, and Roper-Hall,²⁷ in his *Middlemore Lecture of 1941*, stated that oral sepsis far exceeded any other form of focal infection. He recommended that every ophthalmic hospital have a dental surgeon on its staff.

Krusin²⁸ reported the case of a man, aged 50 years, who had a severe corneal ulcer which did not clear up until an infected tooth was removed. He also described the case of a woman, aged 45 years, who had severe neuralgic pain and epiphora which did not clear up until a residual bone infection from an infected tooth was healed.

Green²⁹ reported the case of a man, aged 47 years, who had a retrobulbar neuritis, with extreme loss of vision in the right eye and marked loss of vision in the left eye. After several infected teeth were removed, there was a complete return of vision in the left eye but only 28-percent return of vision in the right eye.

Holman³⁰ summed up the literature on the question of focal infection, and accepted, with reservations, the relationship between primary foci of infection and remote disease. However, he felt that there was not sufficient evidence to confirm the theory of elective localization, but that the involvement of the eye might be in the nature of an allergic phenomenon, a sensitization of the eye to the bacterial toxins. Wootton³¹ also was of this opinion. It is, therefore, apparent that every form of ocular disorder has been ascribed as secondary to infections of the teeth. This question is also important when surgery of the eye is contemplated.

POSTSURGICAL INVOLVEMENT

Ellett³² stated that he had seen many eyes do badly after operation, but improve after removal of the teeth.

In this connection, one is apt to jump to conclusions too hastily, for who has not had the sad experience of postoperative infection even after eradication of all available foci? On the other hand, consider the small percentage of postoperative infections in the numerous cases in which either no search for infective foci or only a superficial one had been made. This is true not only in cases of emergency operations, on patients with acute glaucoma and on traumatized eyes, but also in the elective surgical cases; the patients with cataracts and chronic glaucoma. One must also remember that at times the removal of infected teeth is not an innocuous procedure.

Okell and Elliott³³ showed that 75 percent of blood cultures following removal of teeth were positive for *Streptococcus viridans*.

King and Lord³⁴ found that 12 percent of lung abscesses resulted from extraction of teeth; while Bender³⁵ reported a case of bilateral thrombosis of the central veins following the extraction of four teeth in a woman, 32 years of age.

NERVE PALSY

W. Russell Brain³⁶ reported a case of 3d-nerve palsy on the right side, following the removal of a right upper lateral incisor. The palsy remained partially permanent.

Bailliant and Schiff-Wertheimer³⁷ reported the case of man with a left 3d-nerve paralysis and bilateral optic atrophy who recovered vision after relief from pressure due to a localized inflammatory mass in the region of the chiasm which resulted from an arachnoiditis following removal of a lower-left-molar tooth.

Is the exacerbation of an eye disease

following the removal of an infected tooth a definite indication of an interrelationship? If they are related, is it a specific or a nonspecific-protein reaction?

I have always believed that these reactions were in the nature of an anaphylactic reaction with a great outpouring of exudate and edema. If the reaction is too severe, the function of the eye may be destroyed even though the disease process is stopped.

Woods² believes that this reaction is in the nature of a Schwartzman phenomenon: the lighting up of an inflammatory focus from a nonspecific reaction, or an allergic shock to specifically sensitized tissue.

Regardless of the mechanism, I think that such a reaction speaks for a close relationship between the infected teeth and the involved eye. Because of the danger of an overwhelming reaction in the eye, too many teeth should not be extracted at one sitting or at too close an interval, and operation on eyes should not be undertaken until healing in the region of the extraction is well advanced.

The next group of disorders are those which result from a reflex irritation of the 5th nerve. These may be due to an infective, or, more frequently, a noninfective chronic irritation in the mouth, often an unerupted wisdom tooth and may involve any part of the eye.

Krusin²⁸ quotes Henry as having found 50 cases of uveitis, out of 700, with dental disorders, and only slightly more than half of these were found to be of septic origin. Bleichsteiner³⁸ reported cases of herpes corneae due to reflex irritations of the 5th nerve, and Wilmer reported a case of unilateral complete loss of vision, cured after removal of an impacted wisdom tooth.

The most common symptom induced by these reflex irritations is a neuralgia, in-

volving either part or the whole of the 5th nerve. Rowland³⁹ claimed that the connection of the teeth and eye via the 5th nerve was a very important cause of neuralgias, either inflammatory or of reflex origin.

Resch⁴⁰ stated that the intimate relationship between septic teeth and general headaches and facial neuralgias has definitely been established. The atypical neuralgias in which the symptoms are less severe but more continuous were more definitely due to etiologic factors such as the teeth. He noted that pain sensation was peculiar to the pulp of the teeth while pressure sensation was registered entirely by the investing peridental membrane. He also felt that migraine headaches may be an allergic manifestation arising from the ptomaines or bacterial proteins from chronic tooth sepsis.

Black⁴¹ maintained that the reflex neuroses were practically always due to irritation of the vital pulp of a tooth, although an occasional case may be due to an impacted tooth. The neuralgias were, therefore, usually due to a thermal or foreign-body irritation of the exposed pulp. He stated that the pulp may be infected yet retain its vitality for a long time, explaining the relationship as follows: The pulp is enclosed in the solid dentin and cannot expand. The blood vessels of the pulp have thin walls and expand when irritated, thus pressing upon the delicate 5th-nerve endings. Therefore, in cases of neuralgia, a tooth sensitive to heat, cold, or pressure should be sought and X-ray studies made for suspected impacted teeth.

Bauer,⁴² likewise, believed that a neglected dental neuralgia may in time become a true neuralgia.

Gardner,⁴³ however, takes issue with these claims. He describes a true facial neuralgia (tic douloureux) as a lancinating, paroxysmal pain in the distribution

of one or more branches of the trigeminal nerve. Most frequently it is intraorbital at the start and later spreads. It affects both sexes about equally and is bilateral in 20 percent of the cases. Because of the location of the pain and its resemblance to the pain caused by a drill on the pulp, the teeth very early are looked upon with suspicion, particularly because an attack is frequently incited by chewing or touching a tooth. In spite of these seeming connections, he claims that no dental condition, however neglected and aggravated, can cause tic douloureux. These sufferers usually have had several and even all teeth removed to no avail, but he holds that a tooth may act as a so-called trigger zone.

It seems to me that any irritation of the 5th nerve is a real neuralgia, whether it is from an unknown cause, the so-called tic douloureux, or from a cause which can be found and eradicated. The pain from the latter can be just as severe and disabling.

REPORT OF CASES

CASE 1. C. I., a woman aged 33 years, came to the office on April 5, 1936, because of an itching of both eyes which had recurred for the past few summers. A diagnosis of vernal catarrh was made and appropriate medication was prescribed. On April 30, 1938, the patient returned because the right eye had been red and painful for one week.

Examination disclosed a patch of scleritis adjacent to the nasal side of the cornea. At this time, she also gave a history of recurrent pains in her joints.

The dental report was as follows: A lower premolar had definite bone abscess, and when removed, free pus was visible. In the upper jaw three nonvital teeth were removed, two of which had putrescent canals.

The scleral infection disappeared com-

pletely within two weeks and has not recurred since. When last seen, on March 15, 1941, fine vitreous opacities were the only remaining evidences of the previous infection.

CASE 2. A. P., a man aged 58 years, came to the Beth Moses Hospital, complaining of pain and redness in the right eye. In 1934, he had been treated by the medical department for rheumatism. He was referred for complete checkup for possible focal infection.

Examination revealed vision to be: O.U., 20/20. There was a scleritic nodule at the temporal side of the cornea of the left eye. This was tender to touch.

A dental checkup revealed many infected teeth. These were treated. The scleritis was cured and has not recurred since then.

CASE 3. A. McL., a woman aged 42 years, came to the office on February 5, 1939, complaining of a sandy feeling that had been present in both eyes for many weeks.

Examination showed vision to be: O.U., 20/200. There was a superficial punctate keratitis involving both eyes. Every tooth possessed by the patient had bad apical infection. Over a period of two months all her teeth were removed. The punctate keratitis began to improve almost immediately after only a few of the teeth had been removed. She has had no recurrence of the condition since then.

CASE 4. W. R. H., a man aged 55 years, came to the office on February 8, 1945. About a week earlier he had developed a pain on the left side of his forehead followed by pain and redness of the left eye. At the present time, the pain had disappeared but he now complained of poor vision in that eye.

Examination. Vision was O.D., 20/50,

improved to 20/25; O.S., 20/200, not improvable. The cornea was hazy and showed many deposits on the posterior corneal surface. The iris was hazily seen. Atropine and hot compresses were prescribed. Two days later tension in that eye rose to 55 mm. Hg (Schiotz), and the appearance of the eye was not changed. The following day the tension was 35 mm. Later that day a tooth was removed, followed by the removal of another tooth four days later. The eye began to improve rapidly, and in less than two weeks, the eye was cured.

CASE 5. H. L., a woman aged 32 years, came to the office on May 16, 1945, because the left eye had been red and painful for five days. She stated that she had never had trouble with either eye before.

Examination. Vision was O.D., 20/20; O.S., 20/70. The left eye showed marked circumciliary injection. There was a dense opacity of the cornea in the pupillary area with deep vascularization. There were many "mutton-fat" deposits on the posterior cornea.

The patient was referred for a complete physical examination, including a tuberculin test and dental checkup. The general physical examination and tuberculin tests were negative, but X-ray films of the teeth revealed an abscess around the upper left premolar. It is interesting to note that the patient at no time complained of pain or tenderness in this area.

Following removal of the tooth, the eye became more red and painful, and the patient felt as if a foreign body was in her eye. Soon the latter began to improve rapidly, so that by July 5, 1945, the eye was white, the deep vascularization had regressed, and the deposits on the posterior cornea had completely disappeared. However, there was still present a fine opacity of the cornea in the pupillary area. Vision was 20/25.

CASE 6. C. I. R., a woman aged 39 years, came to the office in May, 1937, with a history that four nights previously she was awakened by a severe pain in the right eye. This pain, lasting a minute or two, had since recurred several times a day.

Examination. The right palpebral fissure was slightly wider than the left. Corneal sensation was equal in both eyes. Vision was normal, and no pathologic process was found. The next day, the pain was more severe and atropine (1 percent) was instilled although there was no real basis for so doing. In two days, the pains had disappeared completely, and both palpebral fissures had become equal.

On September 15, 1937, the patient returned because of extremely severe recurring pain in the right eye for the past two days. She stated that since her last visit she had had pain every day.

Examination. The cornea of the right eye presented a diffuse desquamation of the epithelium. Local therapy and a thorough but vain search for focal infection were instituted. However, an X-ray film of the mouth revealed an upper right impacted wisdom tooth, which was removed. The cornea cleared up in two weeks. The patient has since remained completely free of symptoms. Her last visit was on May 7, 1944, for a refraction.

CASE 7. F. R., a woman aged 53 years, was originally seen on December 26, 1936, when glasses were prescribed for compound myopic astigmatism.

On February 5, 1939, she returned because the left eye teared a great deal, was sensitive to light, and felt irritated constantly. Her symptoms began a day after an upper left premolar tooth had been extracted, a week before.

Excepting for an eye which was sensitive to light and which teared excessively,

no pathologic change was found. Her symptoms did not disappear until about three weeks later; evidently not until complete healing had taken place in the tooth cavity.

CASE 8. E. S., a woman aged 18 years, came to the office on June 6, 1937, because the eyes felt strained and the right eye had been bloodshot, on and off, for the past year.

Examination was completely negative excepting that the cornea of the right eye and the right side of the face were more sensitive to the touch than the left.

On December 4, 1937, she returned because the pain in the right eye had become severe. The eye showed no pathologic lesion. X-ray examination of the jaw showed that a wisdom tooth was progressing and would probably erupt.

About a year later the tooth erupted, and the pain disappeared. Corneal sensitivity in both eyes became equal.

CASE 9. M. W., a man, aged 38 years, came to the office on August 2, 1943, with a history that for the past several months he had been awakened frequently during the early morning hours by an excruciating pain in the left side of the head. This pain was accompanied by blurring of vision in the left eye. A diagnosis of glaucoma had been made by an ophthalmologist, and he was under treatment with miotics, without amelioration of the symptoms.

Examination. There were no evidences of glaucoma, and no other ocular causes for the pain were found. The patient was referred for a dental checkup, and this was reported as negative.

The neuralgic pains became more frequent and more severe, so that when seen again on October 3, 1944, the patient was extremely despondent. He had lost a good deal of weight and was about to sell a

very successful business which he had spent many years in building up. He was intending to move to the South West in the hopes that a more favorable climate would help the tic douloureux which had been diagnosed.

The patient was again advised to have the teeth checked, but with negative results. In as much as the dentist scouted as absurd the possibility of a connection between the pain and the teeth, I felt that the examination was not conscientiously made. The patient was advised to have another dental opinion.

This examination showed some absorption around an upper left bicuspid, and when this tooth was removed, the infection was found to be much more marked than the X-ray film had indicated. The patient has not had a single attack of pain or blurring of vision since the infected tooth was removed.

CASE 10. S. S., a woman aged 39 years, came to the office on March 17, 1945. A few weeks before a foreign body had been removed from her left eye. It was not embedded. Since then there had been very severe pain in the eye and tearing. No pathologic change was found to account for the symptoms. Hot compresses to the eye were advised.

On March 27, 1945, the patient returned for a refraction and gave the information that about a week after her earlier visit to the office, she had gone to the dentist, who found a very badly infected upper rear molar on the left side. After removal of this tooth, the pain and the tearing disappeared as if by magic.

CASE 11. S. S., a woman aged 49 years, came to the office on April 30, 1938, because of headaches and recurrent severe lancinating pain on the right side of the face. These pains had been present ever

since the removal of the canine tooth on that side.

Ocular examination was completely negative. X-ray films of the jaw proved that the root of the canine tooth had broken off during removal and was still present. The neuralgic pains and headaches disappeared completely upon removal of this root.

CASE 12. R. B., a woman aged 19 years, came to the office on May 3, 1939, because she had had recurrent attacks of pain on the left side of the face for the past month. These were sharp and lancinating in character. They began at the lower part of the face, shot up to the eye, and lasted for a few seconds at a time. Her father, who was a physician, had had her thoroughly examined, but no cause for these attacks were found.

Examination. Vision was O.U., 20/15. The eyes were completely negative for pathologic change. X-ray films of the teeth disclosed an erupting wisdom tooth in the upper left jaw. The dental surgeon advised no interference because it was coming through normally. In a few months the pains had completely disappeared and have not recurred since.

CASE 13. E. E., a man aged 32 years, came to the Brooklyn Eye and Ear Hospital on April 17, 1945, with a history that, a week before, a lower right premolar and an upper right rear molar were extracted because they were abscessed. Soon after the extraction, the right eye became blurred, and the following day he developed pain above that eye.

Examination. Vision was O.U., 20/20. There was a moderate circumciliary injection of the right eye. The anterior chamber was slightly hazy, and the iris markings were not well delineated. A mild iritis was diagnosed, and the pupil was

dilated. A few posterior synechiae were easily ruptured, and with the usual local therapy the eye was completely healed in a few days.

CASE 14. W. L., a youth aged 17 years, came to the Brooklyn Eye and Ear Hospital on November 15, 1937, at which time glasses for compound hyperopic astigmatism were prescribed. Vision with the glasses was 20/20. On March 18, 1939, he returned because annoying spots had appeared before the right eye for several weeks.

Examination. No change was found in his refraction or vision; there were numerous fine opacities in the vitreous. A complete check for focal infection revealed a cyst in the roof of the mouth. This was removed in the dental department.

He was last examined on June 22, 1939, at which time he stated that the spots were not annoying him any more. Examination showed that fine vitreous opacities were still present but that they were greatly reduced in number.

CASE 15. L. R., a woman aged 43 years, came to the Brooklyn Eye and Ear Hospital on March 25, 1939, because vision in the right eye had been reduced for three weeks.

Examination. Vision was O.D., 20/50; O.S., 20/20. There was a patch of exudative choroiditis in the lower periphery, and the vitreous had many large opacities. Examination at the dental department disclosed abscesses of the right lower bicuspid and the left lower molar. Both teeth were removed.

When last examined, on April 27, 1939, only some fine vitreous opacities remained in the right eye and vision was 20/20.

CASE 16. H. G., a man aged 36 years,

came to the office on April 13, 1939, because he noticed that vision in the right eye had suddenly become blurred three days before.

Examination. Vision was O.D., perception of shadows; O.S., 20/15. There was a large patch of exudative choroiditis, temporally, and the vitreous was full of large opacities. There was also a detachment of the retina, above and temporally.

Examination of the mouth showed four upper teeth on the right side to be abscessed, and the jaw under one of the teeth was badly infected.

The teeth were removed, and the jaw scraped. The choroidal exudate cleared up. The opacities became fine and scanty, but the detachment increased in extent and was considered inoperable.

CASE 17. R. L., a woman, aged 40 years, came to the office on May 9, 1931, stating that vision had begun to fail in the right eye one week ago. On the day before, vision suddenly became much worse, and the eye was painful. That night she could not sleep because of pain on the right side of the forehead.

Examination. Vision was O.D. perception of hand movements; O.S. 20/15. There was marked circumciliary injection. The cornea was steamy, and the interior chamber shallow. The pupil was dilated and did not react to light. There were no spots on the posterior corneal surface. The fundus was not visible. Tension was 25 mm. Hg (Schiotz), in the right and 12 mm. in the left eye.

A 0.5-percent solution of eserine was instilled in the right eye until the tension was reduced to 15 mm. and the pupil became contracted. The patient left the office completely free of pain, taking with her a prescription for 2-percent pilocarpine, which she was to instill every hour. On the way home she developed

very severe pain on the right side of the head but she did not return until two days later, at which time the pupil was very irregular and there were many deposits on the posterior corneal surface. Tension was 30 mm. (Schiotz). A diagnosis of iridocyclitis with secondary glaucoma was made. The pupil dilated easily, and a large patch of chorioretinitis in the lower temporal periphery was noted. As the mouth appeared to be in very poor condition, a dental checkup was advised. Almost every tooth had apical infection, and the dentist removed six teeth at one sitting. Soon after, she experienced very severe pain in the right eye and, when seen the next day, the fundus was so full of exudate that no details could be made out. In a few days, the lens became opaque and swollen and the anterior chamber shallow, but there was no increase in tension.

When she was discharged from treatment on October 19, 1931, the eye was white, the lens opaque and glistening white. On December 31, 1936, she returned because of pain in the right eye and forehead, present for two days. The cornea was steamy, and the anterior chamber practically absent. Tension was 60 mm. Hg (Schiotz). A peripheral iridectomy was performed at the Brooklyn Eye and Ear Hospital the same day. The eye has since remained white and

free from pain. When last seen, on October 10, 1945, she had uncertain light projection.

CONCLUSION

In my opinion, the eyes are closely related to the teeth and, in a fairly large percentage of cases, are involved by dental infections. This relationship holds true not only for the frankly infected teeth but also for the devitalized teeth. Reflex irritations of the 5th nerve from dental conditions can cause severe facial neuralgias which may be indistinguishable from the true *tic douloureux*. It may also result in a pathologic picture simulating inflammatory conditions, particularly of the cornea.

Indiscriminate sacrificing of teeth should be avoided, and the opinion of a dental surgeon should be sought. Radical dental surgery, such as the removal of many teeth in too short a time, should be avoided because of the danger of an overwhelming reaction in the eye and the subsequent destruction of sight. The indiscriminate removal of teeth before an eye operation is not warranted. However, teeth showing definite apical infection should be removed. If there is a history of past infection of the eye from focal infection, the devitalized teeth should also be removed.

CONJUNCTIVITIS ASSOCIATED WITH ERYTHEMA MULTIFORME BULLOSA

ERWIN E. GROSSMANN, M.D.

Milwaukee, Wisconsin

The multitudinous terminology used in the designation of disease entities in dermatology has led to a somewhat confused state in regard to the ophthalmologic aspects of some of these diseases. As early as 1866, von Hebra¹ described a skin condition, called erythema exudativum multiforme, which is characterized by an eruption of the face, neck, and the extensor surfaces of the hands, forearms, and legs. Constitutional symptoms were rare or absent. Apparently, ocular signs were also absent or were too insignificant to mention. Yet the literature, though relatively meager, has persisted in the use of this term, with its association to definite inflammatory signs of the conjunctiva. It is apparent that so broad a disease entity as erythema multiforme would be described in a variety of forms, some as affecting one part of the body and others designated as having an affinity for particular organs. Thus, dermatologists have noted that one of the rare forms of this disease not only presents the typical exanthem, but also shows vesicular lesions affecting the mucous membrane of the mouth and of the eyes. This form is characterized by marked constitutional symptoms (fever and prostration) which further distinguish it from the original form described by von Hebra. Furthermore, it has been noted that this rare form of erythema multiforme affects the mucous membrane without involving the skin.² In 1922, Stevens and Johnson³ described a "new eruptive fever associated with stomatitis and ophthalmia." Following this report the condition was frequently referred to as Stevens-Johnson disease. Murphy⁴ described the condition and believed it to be definitely a

pediatric condition. Ageloff,⁵ using the term of erythema multiforme bullosa, reported that this condition occurred (in the reported cases) in an age group of 22 months to 16 years. Other cases, reported since Stevens and Johnson, have used a varied, descriptive nomenclature.

It is noteworthy that only the American literature reports a close association of the disease with sequelae destructive to the eyes. In Edmund's⁶ opinion serious ocular complications were rare and, when they did occur, were caused by secondary infection. In this country, however, destructive lesions were noted by Stark,⁷ Wheeler,⁸ Bailey,⁹ and Rutherford.¹⁰

The disease called erythema multiforme is known to occur in several forms. One that is typical, which may well be termed erythema multiforme bullosa, is characterized by a sudden onset, fever, and prostration, a typical iris eruption, a vesicular stomatitis, and a diffuse conjunctivitis of varying degrees. The vesicles of the mucous membranes of the mouth soon rupture, leaving a raw inflamed area. The fauces may be inflamed and edematous. The conjunctiva is usually involved to some degree but, as a rule, somewhat mildly. Severe types may show chemosis, subconjunctival and conjunctival hemorrhage, and, occasionally, corneal ulcer and symblepharon. The causative agent is unknown, and all reports in the past have noted normal or variable laboratory findings, including blood counts, blood culture, smears and cultures of the lesions, and chemistry of the blood.

A probable causative factor was suggested by Chick and Witzberger¹¹ who because they found Vincent's organisms, believed that spirocheticidal therapy

ought to be tried in such cases. Other workers have not been able to verify this relationship.

That erythema multiforme bullosa is not a rare disease is evidenced by the admission to a hospital of seven cases within a period of six months. These seven cases need not be reported in detail since the symptoms are entirely typical and similar in each case so far as the dermatologic aspect is concerned.

Case 1. A man, aged 18 years, was admitted to the hospital with a case of nasopharyngitis. His temperature was 100.4°F. Examination revealed injection and swelling of throat and uvula and vesicles on the mucous membrane of the mouth. Some of the vesicles had ruptured, leaving raw inflamed areas. There was one ruptured vesicle on the glans penis. The conjunctiva was mildly injected, with slight mucoid nonpurulent discharge. The patient was entirely cured within three weeks. The conjunctivitis was treated with boric irrigations and instillation of 5-percent sulfathiazole ointment.

Case 2. A man, aged 18 years, was admitted to the hospital with a case of nasopharyngitis. His temperature was 101.4°F. The conjunctiva, moderately injected, secreted a mucoid discharge. Within 24 hours, vesicles developed on the buccal surfaces, and the mucoid conjunctival secretion became slightly purulent. Smears taken from the mouth and fauces were positive for Vincent's infection. The patient was entirely cured in 13 days. Treatment consisted of nicotinic acid (200 mg. daily). Ocular treatment consisted of boric irrigations and sulfathiazole ointment.

Case 3. A man, aged 24 years, was admitted to the hospital with a case of Vincent's infection. Examination revealed

bullae and ruptured vesicles of the mucous membrane of the mouth and of the penis. He gave the history of having had three previous attacks, always occurring in the spring and fall. The conjunctiva was mildly injected, and there was a slight mucoid discharge. In this case, it was thought advisable to observe the effects of a course of penicillin. He received 1,000,000 units (intramuscularly) within a period of three days. No unusual effects on the course of the disease were noted.

Case 4. A young man, aged 21 years, was admitted to the hospital with the diagnosis of a case of thrush. He gave a history of having had his first attack of the disease in the spring of 1941, four years previously. Since then he had had a yearly occurrence in the spring of each year. At admission: only mouth and penile lesions were noted, but within five days the typical skin picture was presented. Among the bullae in the mouth and on the glans penis were several which had ruptured. The patient's temperature never rose above 99°F. The conjunctiva was mildly injected, with a mucoid discharge. The patient was well in 14 days, receiving the usual treatment of nicotinic acid combined with calcium gluconate. The ocular treatment was the same as in the other cases.

Case 5. A man, aged 23 years, was admitted to the hospital with an upper-respiratory infection. The patient complained of irritation of the eyes and throat. Examination revealed bullae of the skin, the buccal surfaces, and on the glans penis. The conjunctiva in this case was intensely hyperemic and hemorrhagic, both bulbar and palpebral portions being involved. There was a constant flow of bloody secretion from both eyes. The tears were deep scarlet in color, giving a startling effect as they ran down his

cheeks. The patient was acutely ill and prostrated. His temperature varied between 101° and 103°F. The conjunctiva was bathed every two hours with a penicillin solution (500 units per 1 c.c.) followed by an instillation of 5-percent sulfathiazole ointment. Systemic treatment was the same as for the other cases. Within three days the profuse secretion ceased, and the conjunctiva became less hemorrhagic. Within five days, the latter appeared entirely normal. There was no corneal involvement at any time. No sequelae were noted. Fourteen days after admission, there were still some bullae in the mouth and on the glans penis, but they appeared deflated. Eighteen days after admission the temperature dropped to normal. There were, however, bullae still present in the mouth.

Case 6. A young man, aged 23 years, was admitted to the hospital with a case of nasopharyngitis. He presented the typical iris lesions on the soles, abdomen, trunk, arms, and legs. The lesions were maculopapular with vesicular centers. There was one small bulla in the mouth. This patient had no ocular complaints, and results of ocular examination were entirely normal. However, he received the same treatment as the other patients.

Case 7. This patient, a man, aged 24 years, experienced the acute episode of this disease at another camp. His record indicates that he was admitted to the hospital in a state of severe prostration, with a temperature of 103°F. He had a profuse vesicular and bullous eruption involving most of the skin and buccal surfaces and the conjunctiva.

COMMENT

Several interesting points were brought out from the record of the first six acute cases seen: (1) The range of age in this

group was from 18 to 24 years. (2) All cases occurred in males. (3) In two of the six cases, smears from the mouth and fauces showed Vincent's infection. (4) From a systemic viewpoint, five of the cases were comparatively mild; yet they presented bullous lesions in the mouth, and four of them on the glans penis. All five of these patients complained of conjunctival irritation, and all showed mild hyperemia. In no case was the secretion frankly purulent.

Of the seven cases, case 5 was the most severe. There was marked prostration, fever, and dramatic bleeding from the conjunctiva. The secretion, however, never became purulent.

All patients received warm boric irrigations followed by the instillation of 5-percent sulfathiazole ointment into the cul-de-sacs. The one severe case was treated, in addition, with instillations of a penicillin solution every two hours. None of the patients suffered severe ocular complications. All were treated systemically with nicotinic acid and calcium gluconate and one received 1,000,000 units of penicillin (intramuscularly) without remarkable results.

Four of the six cases showed little, if any, skin lesions. The manifestations were confined to the mouth and penis. These four can truly be designated examples of Stevens-Johnson disease.

All of the patients, when admitted to the hospital, were diagnosed as having either nasopharyngitis or Vincent's infection, indicating that some degree of generalized malaise and upper-respiratory symptoms were always present.

The degree of involvement of the mucous membranes of the mouth did not parallel the systemic course of the disease.

Laboratory studies of all cases resulted in normal or variable findings, including blood counts, blood culture, and smear and cultures of the lesions.

The seventh case, which was not seen here during the acute phase, was the only one to exhibit any destructive sequelae. This case had been described as presenting vesicles involving the conjunctiva. When seen here, there was a marked deposition of connective tissue confined to the palpebral tarsal conjunctiva of all the lids. The connective tissue was laid down in whorls, strands, and plaques, so that little normal conjunctiva could be recognized. There was no symblepharon. The patient complained bitterly of conjunctival irritation and the Schirmer test revealed a marked deficit in the lacrimal floor.

CONCLUSIONS

The conjunctivitis of erythema multiforme bullosa has been recognized as an entity and has been given a varied and bizarre terminology. The condition is frequently observed, and when disassociated from typical skin lesions is probably not recognized. Each of the cases here reported was associated with some degree

of catarrhal conjunctivitis, but none became malignant and destructive, as has frequently been described by various writers. The cause is as uncertain now as it was to von Hebra in 1866. In one of my cases, treatment with penicillin brought about no remarkable improvement. The conjunctivitis apparently is checked by either sulfathiazole or penicillin therapy but, in the series reported, this treatment appears to be prophylactic rather than curative. There seems to be no question that the disease is accompanied by a definite systemic disorder, which may, in turn, invite a secondary infection, causing some of the virulent effects reported in the literature.

The association of herpes simplex to erythema multiforme, as recently reported by Anderson,¹² may also give some clue to the cause of the more serious cases. It remains to be seen whether the advent of sulfa drugs and penicillin will have any deterrent effect upon virulent cases.

NOTES, CASES, INSTRUMENTS

RETINAL VENOUS SHEATHING IN MULTIPLE SCLEROSIS: REPORT OF A CASE

HOBART C. JOHNSON, M.D.

Mankato, Minnesota

Since the description by Rucker,¹ in 1944, of sheathing of retinal veins in some cases of multiple sclerosis, no confirmatory reports have appeared in the literature. The case to be reported here resembles those he described and seems

Repeated ophthalmoscopic examinations showed no evidence of any inflammation of the nerve head. On June 9, and July 14, 1944, notations were made that no perivenous sheathing was found. On the latter date, six weeks after the onset of visual loss, the acuity and fields were normal. The tentative assumption at this time was that this was the first episode in multiple sclerosis and that in later years other symptoms would present themselves.

Fig. 1 (Johnson). Fields plotted on June 9, 1944, with 35/330 white target. Dense central scotoma and peripheral contraction in right eye. Fig. 2, Fields plotted on February 3, 1945, with 3/330 white target. Ring scotoma.

to shed light on the nature of the sheathing. Stimulated by the aforementioned article and having had the privilege of observing some of the cases there reported, I was on the lookout for retinal venous sheathing in the cases of multiple sclerosis which came under my observation.

REPORT OF CASE

A white woman, aged 20 years, complained on June 5, 1944, that she had lost the vision of her right eye three days previously. Visual acuity in the right eye was reduced to perception of motion and that of the left was 20/20. Fields were charted weekly for five weeks. Perimetric fields, plotted on June 9, 1944, with the 35/330 white target demonstrated a dense scotoma in the field of the right eye (fig. 1).

Fig. 3 (Johnson). The fundus of the right eye on November 6, 1945, showing two small white plaques overlying a branch of the superior temporal retinal vein about four disc diameters from the nerve head. The dark shadow below the center of the picture is an artifact.

On February 3, 1945, there was again a diminution of visual acuity in the right eye, vision being 20/40 in the right eye and 20/20 in the left. At this time there was a ring scotoma in the field of the right eye (fig. 2). Ophthalmoscopic examination disclosed a moderate pallor of the optic disc, but only a suggestion of pallor in the disc of the left eye. No evidence of perivenous sheathing was found.

In March, 1945, a neurologist, after making a complete examination, confirmed the diagnosis of multiple sclerosis. On October 26, 1945, fields were again plotted and found to be essentially normal. Visual acuity was 20/20 in each eye. By means of the ophthalmoscope, how-

ever, definite sheathing was observed along both superior and inferior temporal branches of the retinal vein in the right eye, about four disc diameters from the nerve head. Two of the plaques are shown in figure 3.

This case indicates that the thin sheathing of retinal veins encountered in some cases of multiple sclerosis is not congenital tissue, but that it appears during the course of the disease of the central nervous system. Rucker,² in a second series, had no case such as this, in which careful ophthalmoscopic examination had been made prior to the finding of sheathing, and thus was unable to state when it appeared.

TANTALUM ENUCLEATION IMPLANT

CARL D. F. JENSEN, M.D.
Seattle, Washington

The high incidence of enucleations observed in the Armed Forces has accentuated the problem of orbital implants. I have used vitallium spheres and lucite spheres and have also observed post-operatively their use by other surgeons. The percentage of rotation out of the muscle cone was frequent enough to be considered disappointing. The percentage of extrusion of the implants was also disproportionately large. I have not used nor seen the results of the implant described by Eggers.¹

After observing the many excellent results obtained by the brain surgeons in using tantalum plates in repairing cranial defects, I was prompted to experiment

with the same element in making orbital implants.

Tantalum has a characteristic bluish-gray color, having a density of 16.6 gm.

Fig. 1 (Jensen). Four-leaf pattern of tantalum, and leaves bent to form a round cup.

per cubic centimeter. It compares favorably with stainless steel in its drawing,

Fig. 2 (Jensen). Operation to insert implant.

stamping, or forming characteristics. The chief value of tantalum to the surgeon lies in its chemical property, which permits cells to obtain their normal growth unhampered. Some investigators have demonstrated the attachment of fibroblasts to the metal itself.

The implant was made by using a .015-in. thickness of tantalum. With the aid of tin shears, a four-leaf pattern was made (fig. 1). The plate was then bent into a round cup shape with concave-shaped leaves.

The enucleation operation was performed in the usual manner. The four recti muscles were tied separately, and the insertions were drawn anterior to the equator of the implant. The muscle sutures were inserted through the perforations and tied over the center of the im-

Fig. 3 (Jensen). Good socket the result of tantalum implant.

plant. Considerable care was exercised in closing Tenon's capsule with interrupted catgut sutures. The conjunctiva was closed with black-silk, mattress sutures (fig. 2).

This procedure was used in seven cases. During a period of six months, no rotation or extrusion was observed. The implant obtained an excellent socket (fig. 3), allowing good rotation.

PENETRATING WOUNDS OF THE CORNEA WITH HYPOPYON TREATED WITH PENICILLIN

CASE REPORT

RAYMOND G. INGALLS, M.D.
New York

N. B., a boy aged 6½ years, on August 28, 1945, received a penetrating injury to the cornea of the right eye from a steel table fork. He was seen by me the next day. Examination showed a hard eye with two penetrating wounds of the

cornea, 4 mm. apart, in the 1- and 8-o'clock positions. The epithelium and substantia propria surrounding the wounds were cloudy. The iris was torn in two places opposite the corneal wounds. The anterior lens capsule was split in its upper third, and swollen opaque lens fibers extruded through the rent. A 3-mm. hypopyon was present. There were ciliary injection, lacrimation, and photophobia. Visual acuity was: R.E. light projection; L.E. 20/50+2 corrected to 20/20 by a +1.50D. sph. \ominus +.50D. cyl. ax. 90°.

The fundus of the right eye could not be seen because of the cloudy media. No foreign body was found. The other fundus and media were normal.

The hypopyon was a direct result of infection introduced by penetration of the anterior chamber. The lens was injured, infected, and offered an excellent medium for the development of suppuration. The glaucoma was due to a narrowed filtra-

sion was made in the cornea, 2 mm. below the limbus, at the 12-o'clock position. The anterior capsule of the lens was entered by the keratome. The anterior synechiae were broken by a spatula, and a complete iridectomy at the 12-o'clock position was performed. Thirty cubic centimeters of normal saline, followed by 20 c.c. of penicillin solution containing 3,300 units per c.c., were flushed through the an-

Fig. 1 (Ingalls). Photograph of left eye on the fifth postoperative day, showing considerable lens cortex in the anterior chamber. Fig. 2, Photograph of left eye two months after operation, showing secondary membrane in pupillary area.

tion angle produced by the swollen lens, combined with obstruction of the trabeculae by a plasmod aqueous. Two anterior synechiae, between the injured iris and corneal wounds, were present.

The operation selected was a linear extraction of the lens with complete iridectomy. Substitution of a solution of penicillin for the usual saline irrigation was the innovation which may be of value in this type of case.

Following avertin and ether anesthesia, the skin of the lids and brow was prepared with iodine and alcohol. Solutions of argyrol and adrenalin were instilled into the conjunctival sac; Castroviejo lid clamps were applied; a superior-rectus bridle suture was passed. A fixation forceps was applied below the limbus at the 6-o'clock position, and a keratome inci-

tion was made in the cornea, 2 mm. below the limbus, at the 12-o'clock position. The anterior capsule of the lens was entered by the keratome. The anterior synechiae were broken by a spatula, and a complete iridectomy at the 12-o'clock position was performed. Thirty cubic centimeters of normal saline, followed by 20 c.c. of penicillin solution containing 3,300 units per c.c., were flushed through the an-

terior chamber. This washed out the hypopyon and several fragments of lens material. A drop of 3-percent atropine was placed in the conjunctival sac, with an ointment of calcium penicillin containing 1,000 units per gram. Both eyes were dressed and protected by a double Ring mask.

An injection of 1,500 units of antitetanus serum was given intramuscularly at the time of operation, and typhoid vaccine, in the amount of two million organisms, was given intravenously the following morning, 14 hours after the anesthesia.

On admission, rectal temperature was 100.6°F. and, the following day at 12 o'clock, was 101°F. (a questionable reaction to the foreign-protein therapy).

On August 30th, at the first dressing,

the anterior chamber was filled with cortex, and there was a moderate post-operative reaction.

On the following day, the iris pillars were in good position, and the anterior chamber was still full of cortex. On September 1st, the cornea had regained its normal luster.

At this time intramuscular injections of penicillin were started as an additional safeguard; 10,000 units were given three times daily and continued for six days (a total of 170,000 units).

On September 2d, some absorption of lens cortex had taken place; the hypopyon had disappeared; the anterior chamber had completely re-formed and no anterior synechiae were present.

Three days later, considerable cortex remained in the anterior chamber (fig. 1), and the question of the advisability of reopening the corneal wound for further irrigation with penicillin was considered; however, after consultation with Dr. John H. Dunnington, it was decided to await developments.

Improvement continued, and the patient was discharged from the hospital on September 10th.

The eye continued to improve, and examination on October 29th showed a clear cornea, except for two scars, a small

string adhesion between the temporal pillar of the iris and the upper corneal wound (fig. 2). There was an atrophic area in the iris, at the 8-o'clock position, which extended along the pupillary border to the 9-o'clock position. The central area of the pupil was partially occupied by thickened lens capsule dotted with pigment; the temporal iris border of the pupil was adherent to the lens capsule by a narrow posterior synechia. Tension in each eye was normal to fingers.

On October 31st, an estimate of 2.00 diopters of irregular corneal astigmatism in the right eye was obtained by the use of the Javal ophthalmometer (this was not accurate because of poor coöperation). With a correcting lens of +7.00 diopters before the right eye, the patient could count fingers at three feet. The fundus could not be examined because of the presence of a secondary membrane, but there was a good reflex. The fundus and media of the left eye were normal.

At a later date, a discission will be done. The remaining synechia may be separated at the same time.

This report is made to call attention to the possible value of this method of therapy in cases of infected penetrating wounds of the eye.

635 West 165th Street (32).

DR. ORRIE E. GHRIST, *presiding*

THE ROLE OF GLASSES, AMBLYOPIA, ORTHOPTICS, AND SURGERY IN THE TREATMENT OF STRABISMUS

DR. SAMUEL ABRAHAM reported on a study of 551 cases of nonparalytic divergent strabismus in which the error of refraction of the two eyes was not sufficient to warrant a consideration of aniseikonia as a factor. He stated that no ocular pathologic change was present. In other words, his report covered all cases of strabismus in which the error of refraction in the two eyes was approximately equal and in which it could be presumed that at the onset of the condition the vision was probably equal in the two eyes. Dr. Abraham said that glasses were prescribed in 307 of these cases with resulting straightened eyes in 109 (35.6 percent). As to the types of cases, 115 were of the periodic type; 192 of the constant type. Eight patients (69.5 percent) of the periodic type were helped by glasses alone, according to Dr. Abraham, whereas 29 (only 15 percent) of the constant type were helped by glasses alone.

The results were considerably better when the cases were treated within six months of the onset, especially those of the unilateral constant type. Among 144 cases of the unilateral type of constant strabismus, only 12 (8.3 percent) responded to glasses when treated more than six months after the onset. When treated within six months of the onset,

which, he said, happened too infrequently, 45.9 percent responded to glasses.

Examination of the cases revealed that those helped by glasses showed considerably less difference in corrected vision in the two eyes than those not helped by glasses. The difference in vision between the two eyes in those helped averaged about 0.3, whereas the difference in vision of those not helped averaged 0.6.

An improvement in vision by treating the amblyopia in the cases of unilateral strabismus resulted in cure of strabismus in 29 out of 60 cases so treated. In 30 of the 31 remaining cases, the vision in the ametropic eye improved to within 0.1 of that of the other eye, with the result that the strabismus became alternating. It was obvious, according to Dr. Abraham, that treatment of the amblyopia was a definite help in the cure of strabismus and results of the surgery showed that the time taken to give such treatment was well spent.

Surgery in 51 cases resulted in a cure in 45 cases (88.2 percent); that is, functional cure, not cosmetic cure. No case was considered ready for surgery in this group of cases unless the vision in the two eyes was approximately equal.

Orthoptics in Dr. Abraham's report was limited in its meaning to that form of treatment which aimed to reeducate the cerebral area in the production of normal binocular vision and definitely did not include treatment with glasses or treatment of amblyopia. In no case where orthoptic treatment alone was given were any results seen. Where orthoptics was combined with treatment with glasses and amblyopic treatment, the results were never better than in the large group of

cases herein reported without recourse to orthoptics. The results of surgery reported were the results in patients given no orthoptic treatment.

Dr. Abraham's report emphasized that functional cure could be obtained in a very high percentage of cases after error of the refraction, the amblyopia, and the possible structural defects had been given proper attention.

He concluded that there seemed to be no need for considering orthoptics in the treatment of most cases of the nonparalytic convergent strabismus seen.

Discussion. Dr. Harold F. Wahlman pointed out that enthusiasts of one or another method for treatment of strabismus tended to overemphasize their own talent or subject. He agreed with Dr. Abraham that it was necessary to consider all the methods of treatment for strabismus and to use all of them to advantage.

Dr. Wahlman raised the question as to whether the amblyopia in strabismus might not often be due to a mild retrobulbar neuritis which occurs in the course of exanthematous diseases in childhood. It was common knowledge, he said, that the history of a squint frequently contained reference to its onset following an exanthematous disease in childhood. He queried whether the retrobulbar neuritis might not be temporary or permanent, and in its permanent form might not explain some of the cases of amblyopia ex anopsia that were resistant to occlusion or other forms of orthoptic therapy.

Dr. Wahlman emphasized that many of the structural changes in cases of strabismus seen at the time of operation, might be hereditary. He stated that he had frequently been perplexed to explain why many patients' strabismus straightened out very well under the anesthetic before the operation had been performed, when the fusion faculty had been eliminated by the anesthetic. He was interested to know

if anyone could explain the mechanism of such straightening.

Dr. C. H. Albaugh said that he had frequently found it difficult to understand the structural changes seen at time of operation in strabismus of short duration, and was often concerned as to what part this might play, particularly in view of the principle elucidated by Dr. Walter Lancaster of Boston; namely, that each extraocular muscle is more powerful than would be normally required by the job it has to do. Dr. Albaugh also mentioned the factor of partial paralysis of elevator muscles as playing a part in the cause of strabismus.

Dr. Abraham, in closing, said that he had not had sufficient time to discuss the problem of hyperphoria in strabismus, but that he felt that it was very unreliable to try to measure any such hyperphoria in the presence of a high degree of squint because of the tendency of an eye to drift in any direction. He said that he was unable to agree with Dr. Wahlman concerning retrobulbar neuritis as an explanation for amblyopia ex anopsia, but did not wish to take up the time to discuss his reasons for disagreement.

Reporter.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

October 1, 1945

MAURICE L. WIESELTHIER, M.D.,
presiding

THE MARK J. SCHOENBERG MEMORIAL MEETING

Dr. Schoenberg, one of the founders of the New York Society for Clinical Ophthalmology, and its first president, was devoted to phases of ophthalmology in which he had performed pioneering work and in which he had a special interest.

CHECKING OF TONOMETERS.

DR. ADOLPH POSNER set up a tonometer-checking station for the first part of the instructional hour.

EXHIBIT ON GLAUCOMA

The National Society for the Prevention of Blindness presented an exhibit on glaucoma to complete the instructional hour.

GLAUCOMA: SOME SUGGESTED ETIOLOGIC FACTORS

DR. FERDINAND L. P. KOCH presented a modified summary of unpublished notes and data of Dr. Mark J. Schoenberg as a synopsis of some of his views concerning etiologic factors of glaucoma. Dr. Schoenberg established a syndrome of symptoms from disturbances of metabolism within the tissues of the eye which altered the equilibrium of the mechanism regulating the intraocular pressure, resulting in a lowering of the threshold within the eye to the stimuli from various parts of the body.

Dr. Schoenberg believed that there must be some missing factor which probably would be found in a consideration of a principle of general physiology which may be stated as follows: (1) the exchange of food and stimuli between that organ and the rest of the organism; (2) the performance of the special function determined by its own anatomic structure. Thus, the function of any organ depends not only upon the impulses, nutrition, and stimuli that are received from the rest of the organism but also upon its independent, specialized, and, therefore, complex structure, which functions as a sort of governor, permitting the organ to maintain its purposive function despite external interference or even lack of external assistance, while simultaneously modifying the effect of stimuli from elsewhere.

The "principle of relative organ autonomy" implies, in the eye, the existence of a stabilizing mechanism to reduce to a proper and harmless degree the continuous stimuli reaching it. This is particularly important since food and stimuli constantly are entering the visual organ in various quantities and intensities, and this would result in varying degrees of functional inefficiency if no regulatory mechanism were present for constant maintenance at a certain level of both nutrition and tension. These levels may vary slightly within very narrow limits.

Certain circumstances or conditions external to the eye—such as: emotional aberrances, abnormalities of blood pressure, physical fatigue, decreased systemic resistance with inflammatory episodes, endocrine disturbances as well as those of metabolism, and others—which may induce some elevation or depression of the intraocular pressure beyond the limits of normal, may manifest themselves in the eye through alterations of: (1) capillary pressure in the uvea; (2) vascular permeability; (3) impairment of ocular drainage; or (4) some combination of the three. The fact that the intraocular pressure, in the great majority of such general situations as have just been mentioned, tends to remain within normal limits appears to suggest the presence of an ocular-tension-stabilizing mechanism. Similarly, since it is not sufficient merely that nutrition, stimuli, and hormones be brought to the tissues, but that these be utilized normally, it might be assumed that a local regulatory factor for these activities must be present.

The theory of an autonomous mechanism assumes that a certain substance or substances are available constantly to control ingress and egress of fluids, gases, and stimuli that determine the normal maintenance of intraocular pressure as

well as the normal metabolism of lens, vitreous, retina, and optic nerve. This assumption implies the secretion of a substance produced in the ciliary processes, which alone of the ocular tissues have a location and form, in addition to their physiologic and histologic characteristics, suited to the secretion of such substances. The functions of these secretions are presumably capillarotonic, neurotrophic, and the maintenance of equilibrium between ocular-fluid inflow and outflow.

The inability of the vitreous to absorb more fluid than it already contains can be reconciled with the many indications that swelling of the vitreous occurs in glaucoma by assuming that the ciliary processes furnish to the vitreous an increased amount of so-called residual protein which seems to constitute its hydrophilic substance.

The continued progression of glaucomatous optic atrophy after a successfully performed decompression operation, which should be arrested if hypertension were the only cause, may indicate the presence in such eyes of a toxic substance that continues to effect a failing of the function of the neurotrophic-producing substance of the ciliary processes necessary for the nutrition of the optic-nerve fibers.

Relaxation of the capillary tonus with dilation increases capillary permeability. In addition to the remote control of the vegetative nervous system, it is conceivable that the ciliary processes furnish a secretion, the failure of which results in various degrees of capillary dilation.

Draining of the ocular fluids (aqueous, intercellular fluid, and venous blood) is, then, more than merely a mechanical problem. Normally, only as much blood as the tissues demand enters the finest arterioles and capillaries, and the local venous system is adequate for its drainage. Similarly, only as much aqueous as the pectinate

ligament, Schlemm's canal, and the perivascular spaces can drain off enters the eye by filtration, dialysis, or secretion. The delicate adjustment is inhibited or stimulated through the vegetative nervous system and the substances furnished by the ciliary processes. If the latter fail, the efficacy of the drainage system may be greatly reduced.

Accordingly, the factors determining maintenance of normal intraocular pressure and nutritional equilibrium are: (1) capillary circulation; (2) physico-chemical constitution of the blood; (3) mechanical agencies and structure of the globe; (4) the secretion of the ciliary processes. Any one of these may undergo alteration, with subsequent incoördination of the others, and produce various types of glaucoma which may be classified as belonging to the vascular, metabolic, drainage, mechanical, and secretory, or to the mixed groups. Buphthalmos would be placed in the drainage category; acute glaucoma in the vascular and secretory group; simple glaucoma in the secretory group only; an absolute glaucoma would represent terminal stages of the mixed types.

Another principle of general physiology is that stimuli will have an effect upon a given tissue or organ only when their intensity is sufficient to cross the threshold of resistance, which varies within definite and narrow limits. It is chiefly in organs that are congenitally inferior or diseased that the stimuli are able to cross the threshold and produce symptoms. One of the fundamental changes in glaucomatous eyes is the lowering of the threshold against the entrance of depressing stimuli originating in any part of the organism. Diseases of other organs or systems are not directly the cause of glaucoma, although if deviations from the normal are present in the eye and the threshold is lowered to stimuli which ordinarily would

produce no pathologic effects, they may unchain the glaucoma syndrome. This fact justifies the use of many provocative procedures which indicate no abnormal results in normal eyes, but which yield hypertensive values in glaucomatous eyes when, presumably, the threshold is lowered to the entrance of stimuli from both within and without the eye.

EXPERIENCES IN SCLERAL RESECTION

DR. DONALD W. BOGART said that Dr. Schoenberg was the first ophthalmologist in this country to attempt the operation for the cure of retinal detachment. He had studied at the Gonin Clinic in Zürich and returned to this country to be the first to perform Gonin's operation at the Knapp Hospital.

The need for a new technique in the surgery of retinal separation has long been apparent. This new procedure may be designated, for want of a better name, "scleral resection for the relief of retinal detachment." It assumes a shrinkage of vitreous with a resultant need for shortening the globe slightly to meet the detached retina with its adhesions to the vitreous. The operation is performed as follows: The sclera is cleared of the appropriate rectus muscle in relation to the detachment. Silk sutures are placed in the muscle for later replacement to its cut stump. Tenon's capsule and any adhesions are cleared.

A 5 by 12 or 14-mm. segment is marked, overlying the equator at the site of the detachment. If such a piece is over the long posterior ciliary artery, part of the segment is removed above and part below it. Two "whip-type" sutures, tied at the ends and placed so as to overlap the proposed incision, are left untied at the middle part. Pulling the two loose ends enables one to close the incision in the manner of lacing a shoe. Tying may be done at any time, if complications

should arise. These sutures are laid aside to permit clear view and removal of the segment. The incision in the sclera is made down to the choroid with a specially designed knife, the blade of which has a sharpened end and a serrated side that guides the surgeon as to the depth of the incision. The latter is made laterally for 5. to 10 mm. and then lengthened to the ends of the marked segment on one side by a scleratome designed especially to protect the choroid by cutting only with its sides.

After exposure of the choroid, the segment is removed with scissors. New forceps have been developed to hold the sclera while this incision is made. Usually, at this point, the subretinal fluid evacuates itself, because of cystic or thinned choroidal areas. The sutures are now drawn up, tied (reinforcement sutures may be used if necessary), and buried.

The area about the closed wound is surface coagulated with a specially designed spatula heated in an alcohol lamp. A limited area is coagulated; the needle is retempered by plunging it at once in sterile alcohol. One or two igni punctures are made with a needle heated in the flame to make certain that all subretinal fluid is evacuated. Ophthalmoscopic control is used during the operation. This procedure is simpler than is diathermy puncture, produces less general ocular reaction, and causes less discomfort to the patient. The muscle is sewed in place, sutures are buried, and the conjunctiva is sewed with running silk. If a tear is present elsewhere, it is sealed off with three or four igni punctures. As a final procedure, 1 c.c. of sterile air is injected into the anterior chamber, after the latter has been penetrated by a Wheeler-type knife, in order to force the sclera, choroid, and retina into apposition. This bubble of air helps restore the eye to normal tension. A 3-percent solution of atropine

is instilled, and both eyes are covered. Convalescent treatment includes bed rest for two weeks and the wearing of pin-hole spectacles for three to four months.

Eighteen eyes, all considered inoperable by the usual methods, were operated upon. Ten of these had been operated on before; 10 were aphakic; three required a second operation. The results were classified on the basis of the degree of reattachment and final vision in relation to the preoperatively estimated *possible* vision (judging by the retinal status; that is, macular damage, hemorrhage). In seven cases the cure was complete; in seven, three-quarters or more reattachment was effected with one-half to three-fourths the possible vision; in three, there was one-quarter to one-half reattachment with one-fourth possible vision; one was a failure.

Myopia was reduced as a result of the operation.

This operation is much less radical than are those previously employed. It is hoped that its adoption, along with the use of the simplifying instruments, will partially solve the problem of retinal separation.

OCULAR DRAINAGE

DR. M. URIBE TRONCOSO opened his address with a brief review of the theories advanced to explain the outflow of the aqueous from the anterior chamber. He mentioned Leber's idea of a continuous current of fluid through Schlemm's canal as well as the theory of dialyzation of the aqueous directly through the blood vessels by an intermittent outflow, a theory which was adopted in part by Duke-Elder. Drs. Troncoso, Friedenwald, and Pierce denied the dialyzation theory and showed that a continuous, although slow, current of aqueous runs out of the chamber angle. Dr. Troncoso estimated that the rate of outflow was about 2 c.c. per

minute, and Drs. Friedenwald and Pierce considered it no larger than 1 to 1.5 c.c. per minute.

The majority of authors who have experimented with animal eyes have stated that the mechanism of the liquid outflow is the same as that in man. The absorption of aqueous is made by osmotic and hydrostatic pressure through the barrier of the vessel walls (blood-aqueous barrier). By detailed study of the comparative anatomy of the angle of the anterior chamber in Mammalia, Dr. Troncoso has shown that there is no Schlemm's canal in the lower Mammalia and that aqueous is absorbed directly through the trabecular veins, which are the superficial branches of the intrascleral venous plexus. In the Primates, Schlemm's canal appears as a distinct anatomic landmark. Its inner wall is covered by the trabeculum, and the aqueous is absorbed directly through it into its lumen. Gonioscopy has shown that, in the living eye, Schlemm's canal is filled, not with blood, but with transparent fluid, the aqueous. However, in pathologic conditions, blood may be seen streaming inside the lumen. This change can also be brought about by tapping the anterior chamber, as Kronfeld and McGarry have demonstrated. Dr. Troncoso believes that, contrary to what happens in the lower Mammalia, in Primates (monkey and man) there is no blood-aqueous barrier, but the aqueous is absorbed directly into Schlemm's canal and from it trickles constantly into the blood stream, without the interposition of a vascular wall.

THE EFFECTS OF RADIATION ON THE EYE

DR. ALGERNON B. REESE said that cataract, the most serious complication from irradiation, starts subcapsularly at the posterior pole and usually remains stationary, with surprisingly good vision. Even when dense, the vision may be

20/30. If the lesion progresses, changes appear insidiously under the anterior capsule, usually two to four years after exposure. Eventually, the lens becomes totally opaque.

The histologic change is necrosis and proliferation of the lens epithelium which produce malformed lens cells and metaplastic fibrous tissue under the posterior and anterior capsule.

Any dose of irradiation capable of producing a therapeutic effect can also result in cataract, if the lens is exposed. No measures, even when expertly applied, can give absolute assurance of adequate protection to the eye. Less than one skin-erythema dose produces a cataract. This is less than the amount needed to produce epilation of the cilia. A dose which will induce no immediate effect (such as conjunctivitis, irritation, or demonstrable changes in the eye) may produce a cataract. Even the spilling from the X-ray tube in treatment of carcinoma of the breast, mouth, and neck, may have this effect on the lens.

A radiation cataract seems less likely to develop in younger than in older people. In the treatment of retinoblastoma, we give 8,000 r at each of two portals, and cataract is a rare occurrence.

If the changes progress sufficiently, surgery is indicated for the treatment of radiation cataract. An intracapsular extraction is definitely preferred, for in extracapsular extraction, the lens epithelium continues to proliferate and form metaplastic, fibrous tissue in the anterior chamber.

Irradiation tends to keratinize epithelium. Keratinization of the corneal epithelium may be particularly annoying. It may occur even following moderate doses of irradiation. In its early stages, this keratinization appears as numerous punctate areas, staining with fluorescein, and may develop into an actual vascularized

pannus. Since the patient is usually directed to close the eyes, these changes are confined to the lower portion of the cornea. When keratinization takes place along the lid margin, it is seen as an extension of a gray line to the posterior margin of the lid or on to the palpebral conjunctiva.

Among the other irradiation effects are: (1) trichiasis, loss of cilia, and regrowth of white cilia; (2) atrophy of the tarsus which, perhaps, accounts for the widening of the palpebral aperture sometimes seen on the side exposed to irradiation; (3) disappearance of the firm elastic tissue along the lid margin, which becomes quite soft and pliable; (4) glaucoma, apparently due to an iridocyclitis rather than stoppage of the trabecular spaces with pigment granules, as sometimes stated; (5) proliferation and migration of the pigmented epithelium of the iris, especially over the lower half (seen as an increase in the number of the clump cells, the appearance of pigment dust over the surface of the iris, and the appearance of pigment deposits on the posterior surface of the cornea); (6) atrophy of the pigmented epithelium of the iris (especially around the pupillary margin and over the posterior surface of the iris in its lower half), permitting light to pass through readily; (7) atrophy of a sector of the iris stroma; (8) later, from six months to two years following the irradiation, vascular phenomena in the retina, such as occlusion of an arteriole or of a vein, the appearance of hard, white deposits, and hemorrhages.

As a result of very heavy irradiation, the central portion of the cornea, or a portion of the sclera (if the focus of the irradiation has been directed over it) may become necrotic and act as a sequestrum. Heavy irradiation may cause necrosis of the conjunctiva, which leads to shrinkage and adhesions between the lids and the

globe, sometimes producing total symblepharon.

In conclusion, three cases of bilateral retinoblastoma, with enucleation of the eye with the more advanced stage and irradiation of the other eye, were reported. In these cases, the heavy X-ray therapy precipitated a malignant neoplasm after arresting the original tumor. In one case, after the patient had had normal vision for eight years, a rhabdomyosarcoma of the temporal muscle developed over the site of a portal for the administration of the irradiation of the eye. This tumor proved to be fatal. At necropsy, it was found that the retinoblastoma, for which the irradiation had been given, was completely arrested. The microscopic examination of the retinal lesion showed tumor cells which did not look necrotic; apparently, however, these cells had lost their power to proliferate and remained in a suspended state of viability following the irradiation. Another patient developed a malignant tumor that also proved fatal to the tissues in the pathway of the heavy irradiation of the eye. A biopsy specimen was taken, but the tissue was necrotic, and the type of the secondary growth was not determined. The third case, seen by Dr. Mark Schoenberg, in 1916, was not subjected to the bilateral enucleation customary at that time, but after enucleation of the eye with the more advanced lesion the patient was sent to Memorial Hospital for treatment by irradiation. The retinoblastoma was successfully arrested, and the patient had 20/30 vision for 27 years. In 1943, a tumor appeared in the temporal region over the site of a portal of treatment. This tumor grew rapidly and proved fatal in July, 1944. The pathologic diagnosis was postirradiation scar-tissue sarcoma.

Irradiation of the region of the eye is never indicated unless the condition for

which it is given is serious enough to justify a treatment that always may jeopardize the eye.

PUPILLOGRAPHY IN THE EARLY DIAGNOSIS OF CHRONIC SIMPLE GLAUCOMA

DR. OTTO LOWENSTEIN said that Mark Schoenberg's last great scientific love was pupillography in connection with the problems of simple glaucoma. In 1941, when they had first investigated the early signs of glaucoma, they thought there might be characteristic pupillographic changes prior to the clinical appearance of manifest symptoms. These might shed light on a nervous factor in the origin of simple glaucoma and simultaneously establish a basis for the diagnosis at a preclinical stage. The studies consisted of following, pupillographically, cases of simple glaucoma and trying to discover whether or not a parallelism existed between consecutive stages of the disease and pupillary disturbances.

A short time previously, Dr. Schoenberg had reclassified simple glaucoma into: (1) a functional spontaneous reversible stage; (2) a predominantly functional stage with slight organic changes; (3) a predominantly organic stage; and (4) the completely organic stage.

It was found that on the basis of pupillography, a purely functional stage does not exist, there being permanent pupillary changes when the clinical symptoms still appear to be functional and spontaneously reversible. In every case these changes showed typical characteristics, differing only in degree, and thereby revealing parallelism with the general development of the disease.

Originally it was believed that these pupillary abnormalities were the expression of destruction caused locally in the iris by the increased intraocular pressure. However, it was found that no cases

of unilateral glaucoma exist in which the seemingly unaffected eye does not show deviations from normalcy on the basis of pupillographic examination.

In previous research, Dr. Lowenstein tried to show how disturbances of pupillary movements in otherwise normal eyes are located either in the sympathetic or parasympathetic centers or pathways. A certain number of symptoms were found to be characteristic of disturbances in part of either the sympathetic or parasympathetic centers.

It was found that certain sympathetic disturbances were present in all of 50 cases of simple glaucoma and that these disturbances, in cases of unilateral glaucoma, included the seemingly unaffected eye. These disturbances could be detected in a very early, preclinical stage of the disease, thus making an early diagnosis possible in otherwise dubious cases. These findings led to the assumption of an at least partly central sympathetic origin of noncongestive simple glaucoma. Demonstrably increased intraocular pressure was shown to be preceded by centrally conditioned pupillary disturbances.

The practical question as to whether or not we may base the diagnosis of simple glaucoma exclusively on pupillographic findings of a central nervous, particularly hypothalamic, type must be answered in the negative. However, where there are clinical ophthalmologic reasons for suspecting the development of simple glaucoma, the absence of central sympathetic disturbances of the type described in cases of simple glaucoma excludes the possibility of glaucoma, whereas their presence makes it likely, although not positive.

Mark Schoenberg died before this work on glaucoma was finished, and pupillographic glaucoma-research work lost its most zealous pioneer and champion.

However, the work is being continued.

Discussion. Dr. Bernard Samuels said he once remarked to Dr. Schoenberg that glaucoma like the poor will always be with us. Dr. Schoenberg's characteristic response was that we must do something against it. Whenever he saw anything that was evil, his first reaction was to attempt in some way to alleviate or get rid of it.

Dr. Schoenberg realized that, in the regular meeting of the Section of Ophthalmology of the New York Academy of Medicine, time and opportunity were often lacking for many young men to show their cases and have them discussed. It is just this need which this Clinical Society, founded and organized by him, so admirably fulfills.

In the last years of Dr. Schoenberg's life he found exactly the proper niche for his talents and aspirations in the National Society for the Prevention of Blindness. Up to that time, he had done a great deal in trying to find out the cause of glaucoma.

The papers on glaucoma presented at this meeting bring to mind a condition that is often referred to as malignant postoperative glaucoma. An eye that has suffered from glaucoma simplex, shortly after an operation of whatever kind, may go into a state of inflammatory glaucoma. The anterior chamber is shallow or abolished; the wound gapes a little; the tension is harder than before; the eye is red and painful and goes on to blindness.

Clinically, this type of malignant glaucoma is generally thought to be due to a subchoroidal hemorrhage, that has not gone so far as to produce a typical expulsive hemorrhage. Microscopically, however, these eyes as a rule show no subchoroidal hemorrhage, but they do give evidence of a swollen vitreous. The vitreous is pushed forward in the circumlental space, the ciliary processes are com-

pressed and directed forward. This swelling of the vitreous would seem to show that it possesses certain biologic qualities of reaction to stimuli although it possesses no nuclei.

MARK J. SCHOENBERG—AN APPRECIATION

ELEANOR BROWN MERRILL closed the meeting with a tribute to Dr. Schoenberg and a description of his achievements as the chairman of the Committee on Glaucoma of the National Society for the Prevention of Blindness.

DR. J. WESLEY MCKINNEY, *presiding*

OLD FOREIGN BODY OF THE IRIS

DR. PHILLIP MERIWETHER LEWIS reported a case of a white man, aged 77 years, seen in August, 1945. In 1890, 55 years ago, while working with brass at his trade of machinist, a piece of metal struck him in his right eye. He was seen by an ophthalmologist, who told him that the brass particle had entered his eye and was embedded in the iris. He was advised to leave it alone. Examination showed an almost completely encapsulated metallic foreign body on the anterior surface of the iris near the pupillary border in the superior-temporal quadrant. The foreign body was apparently slightly more than 1 mm. in diameter. The iris in the immediate vicinity was slightly atrophic, but the pupil reacted normally, and no other abnormality of the eye was present. With a +0.25D sph. \ominus +2.00D. cyl. ax. 180° vision was 20/20. With a +2.50D. sph.

in addition he could read J1. The left eye was normal externally, but there was a senile degeneration of the macula, and vision could not be improved more than 20/200. Neither eye had ever been inflamed or given any trouble since the accident, 55 years before. The patient still worked regularly as a machinist.

TENONITIS COMPLICATING MUMPS

DR. PHILIP MERIWETHER LEWIS reported the case of a white man, aged 34 years, seen six months previously. Both eyes had been quite red and sore for two days. No pus nor mucus was present. There was marked congestion and edema of both eyes, with limitation of motion and marked tenderness. It was noticed that his face was swollen, and examination disclosed that all of his salivary glands on both sides were swollen and tender on palpation. He was thought to have a bilateral tenonitis complicating an acute infection of the salivary glands. His physician considered him to have mumps. He was treated with hot compresses to the eyes and sulfonamides internally. After about eight days his eyes appeared normal except for a slight scleral congestion. It was then noticed for the first time that the tension seemed elevated. Measurement showed it to be O.D., 35 mm., and O.S., 40 mm. Hg (Schiotz). There was no evidence of uveitis.

The regular use of miotics had maintained the pressure at about 30 mm. The peripheral fields had remained normal, but the blind spots were slightly enlarged below. The discs have shown no cupping to this date. Apparently the glaucoma was primary. However, might it not be related, or secondary, to the previous acute condition?

CHICAGO OPHTHALMOLOGICAL
SOCIETY

PETER C. KRONFELD, *president*

CLINICAL MEETING

(Presented by the Department of Ophthalmology, Northwestern University Medical School.)

PRIMARY OPTIC ATROPHY POSSIBLY DUE
TO ARACHNOIDITIS

DR. HELEN HOLT presented C. J., aged 60 years, who had experienced progressive loss of vision until he was unable to work, in 1932. Antisyphilitic treatment had been given elsewhere; blood and spinal-fluid tests gave negative results when the patient was admitted to Montgomery Ward Clinic. On examination, visual acuity was R.E. 8/200; L.E. 4/200, and could not be improved. Argyll Robertson pupils were noted. The discs were white, with sharp margins, but the cribriform plate was not visible. When a large target was used, a visual field was demonstrated to be present on the nasal side of each eye, with constriction above. This field and the appearance of the disc suggested a syphilitic arachnoiditis at the chiasm as the etiologic factor. Operation was not indicated at present. The patient was presented to emphasize the necessity of recognizing the condition early to insure preservation of useful vision.

CEREBRAL THROMBOANGIITIS OBLITERANS

DR. HELEN HOLT presented two patients on whom this diagnosis had been made. Mrs. DeP., aged 52 years, had had encephalitis complicating typhoid fever at the age of 19 years. Since 1935 she had been subject to convulsive seizures with loss of consciousness. Encephalograms showed cortical atrophy, especially frontal and occipital. Mild peripheral vasospasm with no evidence of obliterative disease, was found. The blood pressure

was 164/102. Visual acuity was 20/20; external examination was negative. The retinal vessels showed early arteriosclerotic changes. In addition there had been thrombosis of the superior temporal artery with formation of new vessels just above the macular area. The retina supplied by this vessel was atrophic, with pigment irregularity. The patient illustrates retinal thromboangiitis obliterans with cerebral thromboangiitis obliterans.

Mrs. V., aged 41 years, had what had been diagnosed in retrospect as encephalitis complicating la grippe or influenza in 1942. During convalescence the patient was annoyed by a transient diplopia, but not much paresis could be demonstrated. In January, 1943, a violent headache was followed by aphasia, numbness of the left side of the face and left arm, lasting about one-half hour. Personality difficulties were a constant trial, for she could not adopt an adult status toward her home problems. Psychiatric consultation was of only moderate help. In January, 1945, accommodative ability was lost following a severe headache. Three weeks later alexia for words but not numbers suddenly appeared and has persisted, and a right homonymous hemianopia developed. Peripheral vascular spasm was noted on testing. The encephalogram showed cortical atrophy. A preoperative diagnosis of cerebral thromboangiitis obliterans was made and was confirmed by Dr. Loyal Davis when a right osteoplastic craniotomy was performed. Visual acuity continues to be 20/15. The retinal vessels show no abnormalities. This patient illustrates marked peripheral vasospasm, cerebral thromboangiitis obliterans, with considerable cerebral atrophy and no ocular involvement.

ARACHNOIDITIS

DR. HELEN HOLT said that Mr. J. A. had been presented before this group sev-

eral years ago. In 1936 he had been successfully operated on for a nonspecific arachnoiditis and was presented now to show that visual acuity and peripheral fields are maintained after surgical correction of the constricting bands.

RETINOBLASTOMA

DR. HELEN HOLT said that Sandra R., aged 4 years, had undergone an enucleation of the left eye at the age of 18 months because of a retinoblastoma which filled the vitreous cavity. Tumor masses were noted in the right eye. Seven days after the enucleation, September 15, 1942, intensive X-ray therapy was given to the right eye through the temple region and left border of the nose, according to the standards set up by Dr. Reese. Within the next six months a total of 19,800 r was given. The tumor masses flattened and were replaced by shiny white tissue. On the last fundus examination, May 18, 1945, the lenses were clear; no active tumor tissue was visible. No accurate visual acuity could be obtained, but the child seemed to play normally. Her general status has improved remarkably. The prognosis as to life is good and for useful vision fair.

ARTERIOSCLEROTIC RETINOPATHY COMPLICATING CATARACT

DR. HELEN HOLT said that Mrs. H., aged 65 years, had been a known diabetic for 12 years. On admission her blood pressure was 154/90, blood sugar 384. Diabetic management was instituted. Visual acuity was light perception and projection in each eye. Posterior findings were obscured by mature senile cataract. When the diabetes was controlled, intracapsular cataract extraction was performed on the left eye on December 21st, on the right on January 6th. The postoperative course was uneventful. Visual acuity could not be improved above

10/200. In the fundus of the right eye a delicate gray tissue extended into the vitreous in front of the macula, and the macular area was replaced by a yellow atrophic spot with pigmented borders; in the left eye there was a round atrophic spot in the macula about one-fourth disc diameter in size, with a pigment border; just temporal to this was another patch with a pigment band joining the two. Since then, the arteries of the right eye have become almost imperceptible, and the arteriosclerotic changes are becoming more marked. Gradual closure of the central artery seems to be in process.

TAPETO-RETINAL DEGENERATION

DR. HELEN HOLT said that D. R., a woman aged 29 years, had been presented before this Society in 1939 and 1941 as a case of retinal angiospasm with progressive retinal degeneration. Now the pigmentary changes in the periphery of the retina and the macula with secondary partial optic atrophy, narrowed arteries, and nystagmus, tend to place this case in the category of tapeto-retinal degenerative lesions.

PARINAUD'S CONJUNCTIVITIS

DR. PAULSON said that Miguel, aged 11, had a red left eye with tearing, little purulent discharge, and pain. When examined, the conjunctivas of both lids and globe were velvety red and thickened. The cornea was clear. A diagnosis of conjunctivitis was made, and sulfathiazole was prescribed for local use. The smears were negative. Two days later the eye was slightly improved but the bulbar conjunctiva had a mottled yellow-red appearance with swelling more noticeable on the temporal side. Smears and cultures were negative. Two days later, the temporal area was pointing, and the preauricular gland was enlarged. The patient was hos-

pitalized in Cook County Hospital, the pointing area was incised, and cultures made, which proved to be leptothrix. Recovery was complete following the local and systemic use of sulfa drugs.

ALLERGIC KERATITIS AND IRITIS

Mrs. K., aged 30 years, had suffered from recurrent attacks of keratitis and iritis and was seen at the Montgomery Ward Clinic in the spring of 1944, during an acute attack of iritis. She was hospitalized for clinical study and foreign-protein therapy. No focus of infection was found, and no irritant was proved by allergy tests. Elsewhere it was demonstrated that she was sensitive to peanuts, and she realized that indulgence in this food always precipitated attacks. The patient was not seen for more than a year, but has suffered recurrent attacks which have subsided spontaneously. At present, examination shows many faint macular scars in the cornea from attacks of keratitis. More careful allergy studies should be made, and treatment given to prevent further ocular damage.

CHORIORETINITIS

DR. IRVING PUNTENNEY said that Mrs. D., aged 51 years, was examined in 1943, when the vision was found to be 20/50 in the R.E. Recently, there had been a diminution to 20/200. The patient had not been aware of any visual difficulty and had had no illness. On examination, a dense gray film of tissue was found beneath the retinal vessels and above the choroid in an area above the disc, extending around on the temporal side for a distance of 0.5 disc diameter. The macular area was atrophic and granular. No evidence of perivascularitis was noted. The left eye was normal. This patient had previously been treated for syphilis, but for several years tests had been negative. Since this lesion was entirely healed at the time of examination, no further study was made. The similarity of the old lesion to an active one produced by Brucellosis in a private patient examined on the same day prompted presentation of this case. Consideration of Brucellosis as a cause of chorioretinitis should not be overlooked.

EMMA S. BUSS, *Manuscript Editor*

KATHERINE FERGUSON CHALKLEY, *Assistant Manuscript Editor*,
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to *Mrs. Katherine F. Chalkley*, Lake Geneva, Wisconsin. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, *Mrs. Katherine F. Chalkley*, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

EMMA S. BUSS (1887-1946)

It is with heavy heart that the Journal notes the death of its distinguished and loved manuscript editor, Miss Emma S. Buss. She died quietly in sleep at twilight on August 18, 1946, of cerebral embolism that had swiftly cut her down on the preceding day, in full activity.

Miss Buss came to the Journal as manu-

script editor, fully qualified for this meticulous task by a fine training in the preparation of literary and scientific manuscripts. Her knowledge of and interest in the art of written English had great influence upon the literary style of many contributors to the Journal, particularly among the younger authors whose first ventures invariably received her special sympathetic and tactful treatment.

Restricted in her activities by delicate

health and physical handicap, she devoted her life to her religion and to the Journal. These were her two loves and in them she found happiness and satisfaction. The pages of this Journal for the last 15 years reflect her painstaking care and affection. They are the true monument to her memory and tributes to her skill and devotion.

To many she was but a kindly, often uncompromising name. To those who were her coworkers she was a vibrant personality, jealous of the Journal's prestige, a stickler for style, form, balance, and always the right word. Her knowledge of Ophthalmology absorbed from these many years of painstaking work and extensive reading was truly remarkable. One could safely count on her to pounce upon an error in ophthalmic information as well as one in verbal expression.

She looked upon the contributors as her own people and members of the family. She appreciated news of their activities and items of personal interest. She followed their careers with maternal eye, rejoicing in their success and grieving over the lost ones. This is all the more striking because she had met few of them in person. To her they were very real men and women and her friends.

Ophthalmology has lost a staunch champion of great integrity, ophthalmic literature a gentle puritan, and the Journal its right hand. We salute and honor this gracious Christian lady.

Derrick Vail.

OPHTHALMOLOGY IN THE VETERANS' ADMINISTRATION

Almost any magazine that one picks up nowadays is apt to contain an article about the Veterans' Administration. Gratifyingly, the tone of these is changing. Whereas a year or more ago, most of them were condemnatory, the later ones are usually laudatory. This is largely due

to the attitude of the new director, Gen. Omar Bradley, and of Gen. Paul R. Hawley in the medical field. The main idea is to give effective service to the veteran without overconsideration for previous rules and regulations. The medical profession was at first very dubious about the whole business, fearing socialization and state medicine, but since the doctors are pretty well satisfied now that this is not in the back of General Hawley's mind and that he is eager for constructive criticism and wants to allow the doctors themselves to have a voice in the planning and in many instances will permit the veteran to choose his own doctor, they have begun to swing into line, praising the efforts of the Veterans' Administration to do a good job.

Let us glance at the overall plans for medical care and then at some details about the ophthalmologic needs and how they are being met.

For administrative purposes the nation has been divided into 13 areas. A supreme consultant has been placed in charge of each branch of medicine, under whom are 13 senior consultants, one in each area. In most areas there are about eight veterans' hospitals—slightly more than 100 in all.

Employment of physicians may be on several different time bases; as, for example, on full time. In the ninth area, the ophthalmologists on this status were also doing otolaryngology when these hospitals were visited in May of this year. The few of these who were employed were mostly young men who were inadequately trained because specialty training has not previously been available to many, owing to the lack of facilities for giving this type of instruction. Also, there are no replacements for those men who wish to take courses elsewhere than at their own posts, as they are now permitted to do. These full-time men are most important

to the hospitals because they are always available and can afford to give unstintingly of their time.

Consultants on part-time—presumably mostly on half-time—service have proved important in the set up. They are usually older than the full-time eye specialists and have more experience. Many are certificated by their Boards and have had considerable surgical training. There are definite drawbacks to this form of service, however, in cases where the responsibility for the conduct of the specialty rests solely on these part-time men. To attract these older men it has been necessary to allow them such salaries that dissatisfaction has been occasioned in the full-time group. Their salaries have approached those of the full-time men, and they have had the further advantage of having half time in which to build and carry on a private practice. Often they have had to perform the functions of full-time men because of lack of the latter. If they are to be employed at all, their function should be primarily as instructors to the young men in the full-time appointments, most of whom will have the status of residents. They should supervise systematic courses of instruction, where basic courses in medical schools are not available, covering most of the phases of ophthalmology as well as giving the help usually expected of a consultant, such as advice and surgical assistance.

A third type of helper is the ophthalmologist retained on a fee basis. This physician functions in either or both of two ways; first, by seeing such patients as are sent to his private office from the regional offices and for which consultations he is paid by the visit (these offices usually represent the veterans' non-hospital centers in the area); or second, by making visits to a veterans' hospital on request.

A recent tour of the veterans' hospitals

in the ninth area—Missouri, Kansas, Oklahoma, and Arkansas—gave a picture of all of these methods. In passing, a word might be said commending the foresight of whoever selected the sites of these hospitals and designed the hospitals. Invariably they are located in the highest part of a city or town, in commanding situations with beautiful views. The buildings are, for the most part, modern, well-designed, and well-equipped, although a few are modernized old army-post hospitals. It might also be added that the administrators and chiefs of the medical services give an impression of real interest in their work and of a high grade of efficiency. They seem so keen for the new order that one would have thought that it had originated in the minds of each or at least was just what they had been awaiting through the years. There is, however, some uncertainty as to how much authority each element has in the organization: the dean's committees, the managers, and the branch consultants. The arrangements are all new, and these matters will have to be worked out gradually.

But to return to the methods of employment, in only two of the eight hospitals was there a full-time ophthalmologist and otolaryngologist, and in none a full-time ophthalmologist. Everywhere the former at least was badly needed. This man should be the one doing the major part of the ophthalmology. Instead, his work was usually being done less effectively by one or more consultants whose visits to the hospitals were often intermittent, somewhat casual, and sometimes at the convenience of the consultant rather than at that of the hospital.

Primarily, this would seem to be because the young men who would be desirable for the full-time service have not been interested. One may ask why this is so. In the first place the Veterans' Ad-

ministration has been disparaged by physicians and laymen. One of the most important services that the many new consultants can do for the Veterans' Administration is to talk it "up," not "down." Broadcast the good name that it now deserves, and also, of course, make it a better place for training young men.

This introduces the next point: training. The young man wants to go into a residency where he will get good instruction, a residency so good that it will be accepted for training by the American Boards. Can the Veterans' Administration put on this kind of a program for its young men? In certain of the hospitals this might be done in the following manner. In the first place veterans' hospitals wherever possible should be closely integrated with medical schools. Where graduate training is already being given in these schools, arrangements could be made for the veterans' hospital residents to attend the lectures. Where such programs have not been set up, it might be possible to conduct correspondence courses from medical schools in the area, utilizing the local consultants as advisers in these courses. A stimulating addition to this would be to permit the young residents occasionally to attend one of the recognized basic courses for a week or so at a time. Some of the organizations giving basic training have scheduled their lectures so that they could be handled in this manner. In those areas where no such courses are given, the correspondence courses of the American Academy of Ophthalmology and Otolaryngology might be utilized. The coöperation of the consultants in a teaching capacity is a *sine qua non* for the successful accomplishment of this project.

If some such plans as this, which might lead to complete training for Board examinations, were offered as an attraction, it is likely that there would not be too

great difficulty in signing up residents. But this should be done at once while there are so many veterans seeking specialty training. Since the salaries of veterans' hospital medical personnel are automatically raised 25 percent upon their obtaining certificates of their Boards, it is probable that this would serve as an inducement for them to take permanent positions with the Veterans' Administration.

Lawrence T. Post.

THE ASSOCIATION FOR RESEARCH IN OPHTHALMOLOGY

The fifteenth scientific meeting of the Association for Research in Ophthalmology was held in the Hotel Mark Hopkins Tuesday, July 2d. Eight papers on experimental ophthalmology were presented on subjects varying from experimental dinitrophenol cataract to observations on the aqueous veins. The meeting was well attended and constituted a valuable supplement to the programs of the American Ophthalmological Society which preceded it and of the Section on Ophthalmology of the American Medical Association which followed it. In its 15 years of existence the Association has proved to be a very valuable outlet for ophthalmological research of the more basic type and has brought to the attention of the clinical ophthalmologist many basic studies which might otherwise, in large part at least, have been lost to him in the basic science journals. The Association has drawn together the clinical ophthalmologists especially interested in basic research and the not inconsiderable number of basic science investigators attached to the various university eye departments throughout the country.

In their meeting this year the trustees of the Association decided to take steps which would enable the Association to

function in this direction even more extensively than in the past. It was felt that the Association should be the main meeting ground for the clinical ophthalmologist and the basic science workers engaged with eye problems, including those *not* attached to eye departments. It was pointed out that there are a surprising number of studies of eye interest being performed by anatomists, physiologists, biochemists, microbiologists, geneticists, and other workers in the basic sciences which in general only reach ophthalmologists indirectly in the form of cursory reviews in the abstract sections of our journals.

To encourage these workers to present their papers to the Association, steps were taken to broaden the membership by reducing the membership fees of full-time research workers in the basic sciences and by arranging for the appointment of an increasing number of outstanding basic-science workers to the offices of the Association. It was agreed further that the Association should create a research medal, comparable to the Howe Medal of the American Ophthalmological Society, to be awarded for basic studies of special value. With a view to increasing the availability of basic studies of eye significance to ophthalmologists in general, a committee was appointed to investigate the possibility of developing special basic-science supplements to the established journals to contain comprehensive abstracts or complete articles. The committee is even to consider the eventual publication of an independent journal of investigative ophthalmology.

In a broad sense there are two types of basic research in ophthalmology. The first may be termed original research and is the type requiring the rarer talent. The second type, also of great value, consists in the application to special eye

problems of the tremendous amount of original basic research done by investigators in the various basic fields. This may be compared with the work of the industrial scientist who makes practical application of the discoveries of the pure research worker to special industrial problems. Progress in ophthalmology, as in other specialties, must follow, in large part at least, the progress of basic scientific research, and a primary purpose of the Association for Research is to foster such research and to bring its results to bear as fully as possible on the problems of ophthalmology. It is a great credit to the profession that so many ophthalmologists have recognized the importance of this relationship and that the founders of this Association had the vision to organize a society to promote it.

Phillips Thygeson

RETURN LEND-LEASE

At the close of one of the San Francisco meetings, the members were still delighting in the felicitous remarks of a distinguished British guest. This was not alone for the gracious and easy phrasing, but even more by reason of the precise and interesting choice of words. Perhaps no one realized that singling out this speech was no compliment to the other speakers on the program. This is not the first time that the superior flavor of English medical papers has been noticed.

Very likely this is only another evidence of American adolescence but the time is not too distant when we should be outgrowing our more glaring faults of style, either slovenly, on the one hand, or pretentious on the other. At the same session someone privately criticized the repeated references to "recti muscles." This queer barbarism seems to have caught the fancy of a number of recent speakers. This may be simply struggling

for elegance, or it may be that these authors are overcome by the knowledge that however disagreeable the Romans themselves may have been, they saw to it that their adjectives conformed in number and case to the antecedent nouns. At any rate, some men who would never have been caught saying "obliques muscles" go all out for pluralizing "rectus." So it was "recti muscles," as we say in the Latin.

This is nothing, though, to the French influence. By it Professor Barraquer is deprived of the final "r" of the Spanish, and is Gallicized to "Bar-ra-kay." H. M. Traquar ceases to be Scotch and becomes "Tra-care." Even when the Greeks had a perfectly good word we still have to show off our French. Ophthalmic residents who would never be guilty of pronouncing "shemosis" for chemosis, speak glibly of "shalazion" meaning chalazion. Yet when we could follow the French to advantage, we have to use the Greek derivative to our everlasting sorrow. In the dear dead days you had your eyes examined by an oculist. This was standard procedure. The public was familiar with the word ocular as an adjective, and as the eyepiece of an optical instrument. So there was no uncertainty as to the occupation of an oculist. Today we are ophthalmologists, but what layman knows what ophthalmologist means? This is beside the point in discussing diction, but just how long did it take your secretary to learn to spell the name of your occupation correctly—if she can do it now? Years ago, when oculists were beginning to go out of circulation, one of the journals carried a long paper advocating instead, the use of "ophthalmologist." Uniformity, it said, demands

it. Well, we have achieved uniformity. We stand on the same rarefied plane as the otologists and the rhinologists, names which carry no glimmer of significance to the public. To be sure we might have dropped to the level of the pediatricists, who are popularly confused with corn-doctors. "I know that opto-MEET-rists fit eyes, but what," asked a lovely blonde thing, "is an ophthal-MO-gist?"

This brings up a little clean fun enjoyed by one of the elder statesmen, at the expense of ophthalmologists who use the optometric term "duction," for convergence and divergence. A much neater trick of our lay confreres has been to foist upon us the abuse of "pathology." This is not in the proper abstract sense of the science, or study, but to signify the concrete lesion. "There is no pathology," they say, meaning that no abnormality is noted. Why not say there is no ophthalmology and have done with it. Pathology sounds more rococo, which is reason enough for avoiding it.

If the mischief worked by the radio were to be discussed, there would be no end to this plaint. It would be a comfort, though, to go to just one meeting without hearing someone say "different than" when meaning "different from," or having the ears assailed by the penultimate accentuation, "posi-TIVE-ly" and "evidENT-ly" after the jargon of the announcers.

How about going British enough to act as though we had had an ordinary grammar school education?

They have several things over there to contribute besides island bases.

S. Judd Beach.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

CORNEA AND SCLERA

Pillat, A. The incidence of epidemic keratoconjunctivitis in Styria. *Klin. M. f. Augenh.*, 1943, v. 109, May-June, p. 289.

Pillat reports his observation in 160 cases of epidemic keratoconjunctivitis observed in the University Eye Hospital at Graz during the severe epidemic of 1942. The highest peak was reached in February and a minor elevation in June. In 40 percent of the cases the conjunctiva alone was affected and in 60 percent both conjunctiva and cornea. The diagnosis may be questioned when the process is confined to the conjunctiva, since the disease may be confounded with other diseases such as trachoma, follicular conjunctivitis, and even tularemia. As a matter of fact 27 of the 160 patients had suffered from various eye diseases before the outbreak of the keratoconjunctivitis. In 13 patients trauma had preceded the onset of the inflammation, and in 10 of these a surgical operation. Temporary loss of vision up to 5/36

was observed in 20 patients, but all regained normal or approximately normal vision after a few weeks. The majority of cases occurred in the young and the middle-aged and predominantly in the urban population. In the post-operative inflammations the infection started at least six to ten days after the operation was performed, and it must be assumed that it was transmitted from one patient to another by doctors, nurses, or dressing material. Acquisition of immunity after healing of the disease is probable. There were no definite recurrences. Experimental inoculation of animal (rabbit and guinea pig) eyes failed. Bacteriologic examinations revealed no pathogenic bacteria. Therapeutically it is important to avoid all kinds of dressings in all stages of the disease. Local treatment consisted of instillations of 3 to 5-percent targesin or 3-percent boric acid solution. Sterile horse serum or liquid paraffin instilled hourly were also beneficial. Pillat does not believe that a 1-percent solution of optochin is as specific as has been claimed. Heat is indicated when the cornea is in-

volved. Pillat has the impression that sulfa drugs in large doses contributed to a more rapid disappearance of the irritation of the cornea as well as of the conjunctiva. He is definitely opposed to the practice of considering the three most common superficial corneal diseases (allergic, superficial, punctate keratitis, epidemic keratoconjunctivitis, and keratoconjunctivitis nummularis) as one. They should be differentiated until the etiologic factors are known. (1 map, 3 charts, 4 corneal pictures, references.) F. Nelson.

Sydenstricker, V. P., Hall, W. K., Hock, C. W., Pund, E. R. **Amino acid and protein deficiencies as causes of corneal vascularization: a preliminary report.** *Science*, 1946, v. 103, Feb. 15, pp. 194-196.

In May, 1945, a biomicroscopic examination was made of more than 200 inhabitants of Leiden, The Netherlands, who were selected at random from the population. Ten percent were suffering from famine edema. None of the individuals examined showed corneal vessels. In the rat corneal vascularization develops when there is a deficiency of any of three indispensable amino acids or of protein. Further investigation is necessary before the significance of these findings becomes clear. (References.)

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Beauvieux, J., and Bessière, E. **Sympathetic ophthalmia. Its place in general pathology.** *Presse Médicale*, 1945, no. 44, Nov. 3, p. 593.

The various theories as to the etiology of sympathetic ophthalmia are reviewed. The authors conclude that

the disease must be an infection and note that several clinical observations point to the bloodstream as the source. They report a case of the disease in a man, 61 years of age, who suffered a perforating injury of the left eye which necessitated enucleation 35 days later because of impending sympathetic inflammation of the right eye. With the first signs of irritation in the sympathizing eye the patient noted severe frontal and occipital headaches, partial deafness and humming noises, and evening temperature elevations. Spinal fluid studies showed 543 lymphocytes per cubic millimeter. Treatment consisted of intravenous injections of sodium salicylate and intramuscular injection of electrargol, followed later by a course of penicillin, 630,000 units in eight days. Under treatment the temperature became normal, the headaches and deafness disappeared, and the inflammation of the eye subsided somewhat, although vision had dropped to 0/2. Ophthalmoscopic examination revealed a retinal detachment in the extreme periphery in the lower quadrant of each eye but this subsided spontaneously. Three months after the injury, however, the spinal fluid still showed 400 lymphocytes per cubic millimeter.

The resemblance of this case to Hara-da's disease and to the Vogt-Koyanagi syndrome was striking and the authors conclude that the symptomatic triad of bilateral uveitis, lymphocytic meningitis, and neurologic difficulties belong not only to sympathetic ophthalmia but to other syndromes. They do not believe that this indicates a common etiology but rather that it suggests that different viruses may have similar tissue affinities.

Phillips Thygeson.

Bessiere, E., and Corcelle, L. Uveo-meningitis and Harada's disease. *Arch. d'Ophth.*, 1945, v. 5, no. 3, p. 344.

The authors add two new observations to the literature on the syndrome of bilateral uveitis with meningitic or cerebral manifestations. Neither patient, however, had auditory difficulties, retinal detachment, or pigmentary disturbances of the skin or hair such as are customarily found in Harada's disease. They discuss the nature of this type of uveitis and conclude that Harada's disease is truly a clinical entity but that it is not correct to consider all cases of uveitis with meningeal symptoms as incomplete forms of it. They point out that many of the neurotropic viruses, for example, the herpes zoster virus, may affect both the uveal tract and the central nervous system.

Brues, A. M. A genetic analysis of human eye color. *Am. J. Phys. Anthropol.*, 1946, v. 4, March, p. 1.

Comparisons of siblings provide a better basis for studies in human genetics than analyses of successive generations, since the latter method is limited and often dependent on indirect evidence. This paper demonstrates the methodology of sibling comparison studies, as applied to the analysis of human eye color.

Three hundred subjects were examined. Ten color groups were arbitrarily set up, as well as groupings for secondary iris markings. In all, there were 50 possible color combinations, reduced for simplicity to eight eye color types. To this color analysis, there was added the additional variable of iris structure, for which purpose iris patterns were grouped as: smooth or smooth-striated, cryptose, ridged, eroded or scalloped.

The varieties of eye color, with the criteria of iris structure, could be explained, from this study, by six factors:

1. The first factor, a dominant, was a determinant of heavy, dark irides (smooth, brown).

2. The second factor determined differences between dark smooth and brown-mixed smooth irides.

3. The third was the sex-linked "dark" factor. In this connection it was observed that there was a predominance of darker eyes in women.

4. A sex-linked dominant factor was responsible for the antenatal or neonatal vessel atrophy which produced the "scalloped" or "ridged" iris. In the absence of this factor, the irides appeared "cryptose" or "eroded."

5. A fifth factor was that which rendered the pigmented areas, in a "mixed" eye brown, rather than yellow.

6. A recessive factor responsible for the infrequent truly dark eyes without smooth structure.

The importance of iris structure in relation to color inheritance complicates any attempt to systematize the data in this study, and demonstrates the impracticability of attempting to predict eye color in offspring, or to trace parentage through evaluation of eye color. The only practical value of the study may be in the possibility of predicting, on the basis of dominant sex-linked iris traits, whether normal females are carriers of sex-linked defects known to exist in their families.

Buckler, C. W. Seesaw nystagmus associated with choroiditis and positive neutralization test for toxoplasma. *Arch. of Ophth.*, 1946, v. 35, March, pp. 301-302. (See Section 4, Ocular movements.)

Essen-Möller, Lars. **Pulmonary findings in chronic and acute iridocyclitis and choroiditis.** *Acta Ophth.*, 1942, v. 20, pt. 2, pp. 97-120.

The data are based on pulmonary X-ray findings in 186 cases of chronic iridocyclitis, 140 cases of acute iridocyclitis, 62 cases of sclero-keratitis, and 44 cases of choroiditis. The chest X-ray films of 96 patients hospitalized because of accidents, 325 psychiatric patients, and 21 patients with eye diseases that have no relation to tuberculosis were used as a control. A comparative analysis of the pulmonary findings in the two groups reveals the following facts.

In chronic iridocyclitis active pulmonary processes, mostly at the hilus, were found in about half of the patients, or 10 percent more frequently than in the control group. The pulmonary changes were found chiefly in iridocyclitis with iris nodules and fatty precipitates, findings that clinically suggest tuberculosis or Boeck's sarcoid. The active hilus processes were also apparently of the same origin and could be considered a source of hematogenous infection. There was no greater frequency of active foci or healed scars in the lungs of patients with diseased eyes than in those of the control group.

The frequency of pulmonary lesions, active or healed, in acute iridocyclitis was not greater than in the control group. Clinically, the ocular disease was attributed to rheumatism, gonorrhea, and acute infections.

In sclerokeratitis pulmonary lesions were found with the same frequency as in chronic iridocyclitis; there were scars in the lungs, presumably of tuberculous origin. There was no case of Boeck's sarcoid in this group, and hilus adenitis was found once. The pul-

monary lesions are apparently of a different type from those found in iridocyclitis, and suggest a different pathogenesis. It is particularly interesting that in choroiditis the pulmonary lesions did not exceed those of the control group; hilus adenitis was not found in any of these. Choroiditis is generally believed to be tuberculous, and the lesions in the fundus are believed to be the invasion sites of tubercle bacilli. The data of this study indicate that the relation between choroiditis and tuberculosis needs further investigation.

It is pointed out that the determination of the etiology of the ocular lesions on the basis of pulmonary X-ray findings is not reliable. The tonsils and the cervical and mediastinal glands should be considered as sources of a tuberculous infection. There is also the possibility that pathologic hilus glands and active processes in calcified glands may escape roentgenologic demonstration.
Ray K. Daily.

Essen-Möller, Lars. **The prognosis of chronic iridocyclitis.** *Acta Ophth.*, 1942, v. 20, pt. 2, pp. 121-144.

A detailed analysis of 244 case histories of chronic iridocyclitis revealed that the data were adequate for this study in 86 percent. Seventy-two percent of the patients recovered, and in 42 percent the vision was normal. Forty-two percent had a visual acuity of less than 0.3 and 30 percent were practically blind. Vocational disability between 80 and 100 percent occurred in 20 percent of the patients. The prognosis for recovery and for visual acuity is worse in bilateral lesions. In patients over 40 years of age, the prognosis is poorer for women than for men; in younger patients it is the same in women and men. A rise in ocular ten-

sion occurred in one third of the eyes. A moderate rise of short duration does not affect the prognosis. With a marked and prolonged rise of tension, the prognosis is worse, particularly when surgical intervention becomes necessary.

When pulmonary changes are demonstrable roentgenoscopically the prognosis of the ocular lesion is worse than in patients with normal lungs. The clinical course of the ocular lesion was no different in patients with healed pulmonary lesions than in those with active processes. When there were active lung lesions, the ocular involvement was more frequently bilateral.

Ray K. Daily.

Gonzales-Pola, A. M. The **physiopathology of the intraocular circulation**. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Feb., pp. 79-91.

The autonomic-endocrine imbalance and its relation to the uveo-retinal circulation is briefly discussed. With the development of ophthalmoscopy in red light and retino-photography in infra-red light the choroidal circulation, formerly inaccessible for study, will become better understood, and many of the pathologic processes grouped under the common name of choroiditis will be found to be the results of vascular disturbances. The occurrence of choroidal lesions at puberty and at the menopause indicates that the endocrine glands play an important role in their pathogenesis. The organic lesions are secondary to functional disturbances. Because of the abundant blood vessels of the choroid circulatory disturbances do not cause a necrosis of tissue. The primary disturbance is a slowing of the blood stream due to a lack of vascular tone and defective contractility of the vessel wall. The para-

sympathetic function is diminished with an excess of sympathetic dominance; this leads to vascular spasms, an increased pH, and diminished oxygen content; the latter stimulates the vasodilators and an irregular alternation of vaso-constriction and vaso-dilatation sets in which impairs the function of the choroidal vessels and retinal nutrition. Localized disturbances of this nature result in the development of the choroidal foci, which were formerly considered inflammatory.

The therapeutic difficulties are due to the fact that the drugs that affect the general blood pressure have no effect on the retinal vessels, unless administered inträarterially. Whatever effect on the eye may be obtained through the general administration of mimetic drugs can be fortified by the local use of such drugs in the eye.

Jebejian, R. and Kalfayan, B. The **oculo-bucco-genital syndrome**. Ann. d'Ocul., 1945, v. 178, Aug., pp. 335-344.

Fifteen cases of this syndrome (Behcet) have been reported. There may be recurrent iritis in both eyes and retinal inflammation with hemorrhages and retinitis proliferans. In the lips and mouth recurrent ulcers of the herpetic type occur, and the genital lesions are recurrent ulcers in scrotum and vulva. Erythema nodosum and joint inflammations are less frequent. There is rarely any loss of the general well-being of the patient. Both sexes and practically all ages may be affected. Involvement of the different bodily parts may be mild or severe, complete or incomplete, simultaneous or at intervals. In the author's case, a transient recurrent macular edema in both eyes was first observed in a mechanic, 19 years of age, and apparently in good health.

This was followed by a bilateral iritis with hypopyon, and later by retinal hemorrhages, retinitis proliferans, and ulcers in the lips, mouth, and scrotum. All relevant serological tests were negative. A biopsy from the lip revealed acid fast bacilli resembling those of bovine tuberculosis. In the course of five years the vision of one eye was lost completely because of secondary glaucoma and atrophy. The vision of the other eye was 8/200. This syndrome apparently is a basic constitutional degeneration of definite tissues in several parts of the body, that makes them allergic or reduces their resistance to the organisms or toxins of several bacteria or viruses. (6 figures. 20 references.) Chas. A. Bahn.

Kinsey, V. E., Jackson, B., and Terry, T. L. Development of secretory function of ciliary body in the rabbit eye. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 415-417.

As one approach to the problem of the causation of ocular maldevelopment in premature infants, a study was made to determine when the intraocular fluid assumes its adult character of a secretion. The ascorbic acid content of the aqueous humor and blood were measured in rabbits from birth until the age of 32 days. The concentration in the aqueous was found to increase rapidly after the ninth day, reaching the adult level 18 days later. The ascorbic acid concentration of the blood remained essentially constant. The concentration of ascorbic acid in guinea pigs at birth did not differ significantly from that in the adult animals.

The volume of the aqueous and the volume of the eye increased linearly with age from birth. The ratio of the volume of aqueous to the volume of the

whole eye increased rapidly from birth to reach a constant value at the same time (27 days of age) that the ascorbic acid concentration reached a maximum. John C. Long.

Måhlén, Sven. A contribution to the knowledge of flocculi iridis. *Acta Ophth.*, 1942, v. 20, pt. 2, pp. 153-158.

The literature is reviewed in detail and a case in a 15-year-old boy is reported. There was no relevant family history and his visual acuity was normal. His pupillary borders were surrounded by small brown grape-like bodies, some of which were vesicular. Homatropine produced only moderate mydriasis because the flocculi presented a mechanical obstruction to dilatation. (2 illustrations.)

Ray K. Daily.

Porsaa, Kaj. Papilloedema in iridocyclitis. *Acta Ophth.*, 1944, v. 21, pt. 4, pp. 316-329. (See Section 11, Optic nerve and toxic amblyopias.)

Rasmussen, Knud. Pathologico-anatomic investigation of iritis Boeck. *Acta Ophth.*, 1943, v. 21, pt. 3, p. 214-223.

The enucleated eye of a girl, 12 years of age, presented a microscopic picture of chronic iridocyclitis, that involved principally the ciliary body. The large mass of tissue that adhered to the ciliary body and extended to the lens and choroid consisted of connective tissue with round-cell infiltration, interspersed with larger and smaller conglomerates of typical epithelioid tissue. The literature is reviewed, and it is reaffirmed that clinically and histologically Boeck's uveitis is a special ocular manifestation of a general affection, and not an incidental occurrence of uve-

itis in a patient suffering from Boeck's sarcoid. (4 illustrations.)

Rauh, Walter. The photographic picture of choroiditis centralis serosa. *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 152.

Central serous choroiditis, apparently common in Japan, was thought to be rare in Germany until Meisner pointed out in 1942 that it occurs more commonly than had been assumed. Rauh reports two cases, one of which occurred in a woman, 37 years of age, and the other in a man, 38 years of age. He was able to follow up the increase and decrease of the edematous disc in the macular region and the formation of pigmentation and choroidal foci near the posterior pole with serial fundus photographs. In both cases the characteristic sharp limitations of the edema, the small grayish-yellow spots in the lesion, the development of a choroidal lesion, a slight recurrence, and eventually the total disappearance of the edema could be demonstrated photographically. (13 fundus photographs, references.) F. Nelson.

Rogge, A. J. A case of sympathetic heterochromia acquired in adult age. *Acta Ophth.*, 1942, v. 20, pt. 2, pp. 205-211.

A woman, 49 years of age, developed myosis in the left eye, narrowing of the palpebral fissure, and a partial depigmentation of the iris, which had been normally pigmented. The pupil was displaced slightly nasally. General examination was negative, except for a paralysis of the sympathetic on the left side. The father of the patient had blue and the mother brown eyes. It is believed that this patient had a

latent hereditary predisposition to heterochromia due to incomplete crossing of the hereditary traits from the parents, which became active after paralysis of the sympathetic. The cause of the sympathetic paralysis could not be determined. Ray K. Daily.

8

GLAUCOMA AND OCULAR TENSION

Bailliart, P. Some errors in ophthalmic practice: glaucoma. *Ann. d'Ocul.*, 1945, v. 178, June, pp. 254-257.

The need for frequent changes of glasses in those past 50 years of age, a transient or permanent change in visual acuity, and pain in and about the eyes without objective explanation should suggest tonometry and field measurements. Clinical glaucoma with practically normal tension is easily overlooked. Pilocarpine should be used routinely after tonometric measurements in glaucomatous patients. Tonometric measurements alone are not sufficient to determine the progress of glaucoma; the vision and visual fields are just as important. Paracentral scotomas are easily overlooked. Patients who have glaucoma should be informed that their sight is worse in dull light, and that they should avoid it as far as possible. The progress of glaucoma depends partly upon general well-being, and the patient should avoid caffeine as well as physical and mental excitement and exhaustion. Glaucomatous patients whose tension is not completely under control should be examined at intervals of not more than 15 days. Glaucoma is frequently controlled by miotics but seldom cured, and one must continue the use of miotics even when the tension is under control. When operation becomes nec-

essary because miotics no longer control the tension it should be performed promptly. Orbital alcohol injections do not replace operation. Paracentesis should be avoided in primary glaucoma. Paracentral scotoma may become central after operation. Normal tension after fistulizing operations does not necessarily insure the retention of vision throughout life. After glaucoma operations general health and well-being should be maintained at its maximum.

Chas. A. Bahn.

Coppez, Leon. The pyrometric electrode in Vogt's glaucoma operation. *Ophthalmologica*, 1945, v. 109, Feb.-March, pp. 80-101.

It is not enough to know the strength of the current in diathermy. The factor of greatest importance is the temperature that is produced in the tissue. This can be measured by means of the pyrometric electrodes that the author described several years ago. Tissue damage can only be avoided if the temperature is carefully measured and is known throughout the procedure. The author discusses the physical basis of the method of temperature control in great detail and describes his method of surgical operation. The latter is a modification of Vogt's diathermy puncture; a flat electrode is placed directly on the denuded sclera over the flat part of the ciliary body.

Alice R. Deutsch.

Icaza, M. J. Medical treatment of acute glaucoma. *Arch. of Opth.*, 1946, v. 35, April, pp. 361-365.

As an aid to the treatment of acute glaucoma the author uses a retrobulbar injection of one cc. of a 2-percent procaine hydrochloride solution to which 0.0001 gm. of epinephrine hydrochloride has been added. Pilocarpine and physostigmine are instilled into the eye before and after the retrobulbar injection. This treatment is followed by prompt loss of pain and congestion and the eye becomes soft. Eyes so treated can be operated upon days or weeks later under perfect conditions of tension for the operation, and the patient will not have suffered a recurrence of pain in the meantime. John C. Long.

Jayle, G. E., and Schachter, M. Hypophysis and glaucoma. Statistical study of the characteristics of the arterial pressure in glaucoma. *Presse Medicale*, 1946, No. 4, Jan. 26, p. 51.

The authors discuss the role of the endocrine glands, in particular the hypophysis, in glaucoma and mention the decrease in intraocular pressure which accompanies the physiologic hyperpituitarism of pregnancy. They note that glaucoma almost never occurs during pregnancy and that hypotension is a feature of acromegaly, chromophobic pituitary adenoma, and the syndrome of Babinski-Froelich. In contrast they note the permanent or recurring attacks of ocular hypertension and rise in blood pressure in Cushing's syndrome. They note that in Simmond's disease there is marked arterial hypotension where there is marked hypofunction of the gland. They make a statistical comparison of the arterial pressures in 45 cases of chronic glaucoma and compare them with the pressures in Simmond's disease and Cushing's syndrome. They found hypertension in 75 percent of the patients with glaucoma, in 87 percent of those who had Cushing's syndrome, and in two percent of those with Simmond's disease. They note the importance of age in glaucoma and its

lesser importance in the two pituitary syndromes but conclude that the findings point to a possible pituitary role in the production of chronic glaucoma.

Phillips Thygeson.

Law, F. W. **Glaucoma**. *Guy's Hospital Gazette*, 1946, v. 60, March 16, p. 66.

In this lecture, the author stresses the anatomical factors in the etiology of the various forms of glaucoma. In each instance he refers the ultimate cause to narrowing or obliteration of the chamber angle. Secondary glaucoma is considered briefly, and mention is made of the manner in which such diseases as iridocyclitis, hyphema, subluxation of the lens, and intraocular masses produce glaucoma by their effect upon the chamber angle.

Primary glaucoma is described under the headings of congenital, chronic simple, acute and chronic subacute. The author differentiates between chronic simple glaucoma, which he describes as entirely symptomless, and chronic subacute glaucoma, characterized by symptoms generally described in textbooks under the heading of chronic simple glaucoma.

The treatment of secondary glaucoma must be directed toward the causative factor. In the acute primary type medical treatment should be applied for one or two days before resorting to surgery. Chronic glaucoma should be treated as acute during attacks, using miotics, heat, morphine and dehydration. The aim of all surgery in primary glaucoma is to provide a new area of drainage for the aqueous.

Benjamin Milder.

Rednót, Magda. The origin of hypotony of the eye. Ocular findings in orthostatic hypotony. *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 161.

The term orthostatic hypotony was coined in 1932 by Laubry and Doumier. Formerly the symptom complex was called postural hypotension by Bradburg and Eggleston in 1925. The most pronounced symptoms of the disease are vertigo and unconsciousness accompanied by a rapid decrease of the systolic and diastolic blood pressure as well as increase of pulse rate in the upright position. These patients perspire only slightly if at all. Secretion of urine is increased during the night, when the body is in a horizontal position. The basal metabolic rate is somewhat subnormal. Disturbances of the organs of internal secretion are common. One case of typical orthostatic hypotony in which the author was able to observe a number of interesting ocular symptoms is reported. A man, 57 years of age, had functional disturbances of the hypophysis, but no Addison's disease, tabes dorsalis or other neurological ailments. He was admitted to the hospital because of severe vertigo. He had convergent strabismus with normal vision in the right eye and amblyopia in the left. In the horizontal position the ocular tension was 17 mm. Hg and was not influenced by mydriatics. After several up and down movements of the body it went up temporarily to 22. In the sitting position the tension dropped to six, and the patient complained of vertigo. When the patient stood up tension fell below four mm. Hg, and he lost consciousness. The fundus was pale and pulsation of the retinal arteries was visible. The blood pressure was reduced to 60 mm. Hg. The variation of the ocular tension is a new symptom of

McPherson, S. D. Jr. **Cyclodialysis in the treatment of glaucoma**. *Amer. Jour. Ophth.*, 1946, v. 29, July, pp. 848-853. (6 tables, references.)

orthostatic hypotony. Its decrease is caused by the fall of the blood pressure, a sign of disturbance of the peripheral sympathetic system. The retinal blood pressure was measured with Baillard's and Kukán's dynamometer. Variations in ocular and vascular tension follow parallel courses as in some cases of neurasthenia, poisoning with chloral hydrate, typhoid fever, and particularly in the comatous stage of diabetes. (References.) F. Nelson.

Riddell, W. J. B. Tangential displacement of the iris in chronic glaucoma. *Brit. Jour. Ophth.*, 1946. v. 30, Feb., pp. 74-81.

The author describes a tangential displacement of the radial fibers of the iris in chronic glaucoma. It is certainly a stage in the atrophy of the iris in advanced glaucoma but it can occur early. He briefly describes its appearance in 14 of 35 consecutive cases of glaucoma. Morris Kaplan.

Smith, J. H. The blood-aqueous barrier in hydrophthalmic rabbits. *Ophthalmologica*, 1944, v. 108, Dec., pp. 293-297.

The university eye clinic in Basel successfully bred a strain of hydrophthalmic rabbits with greatly increased ocular tension. A solution of fluorescein sodium was injected subcutaneously into such rabbits as well as into normal rabbits. It was found that the fluorescein appeared later in the aqueous of the hydrophthalmic rabbits and that its flow across the blood-aqueous barrier is, considerably slower than in the eyes of normal rabbits. (References.) Max Hirschfelder.

Weekers, L., and Weekers, R. The hypotensive effect of diathermy on the

ciliary body without perforation of the sclera. *Ophthalmologica*, 1945, v. 109, April-May, pp. 212-226.

The authors describe a modification of Vogt's diathermy-puncture which they call nonperforating cyclodiathermy. They discuss the technique of this operation, its effect on the intraocular tension, its influence on the visual acuity and fields, its possible post-operative complications, as well as its advantages as the operation of choice in chronic, secondary, and absolute glaucoma.

They use the ophthalmic diathermy apparatus on a bipolar current. The active electrode consists of a small cylinder .75 millimeter in diameter and one millimeter long which is fitted to a curved metal arm to control the isolation and limit the penetration. They instill a local anesthetic and prolong anesthesia by retrobulbar injection and warn against the use of subconjunctival injections because of the chemosis which follows. The electrode is applied directly to the eyeball without dissecting the conjunctiva. Pressure is necessary to maintain contact. Eight applications are made seven millimeters from the limbus, in regular intervals so spaced as to avoid the insertions of the ocular muscles. The time of application is 15 seconds. The operation is effective in chronic glaucoma because it produces permanent increase in the lumen of the uveal vessels which results in increased resorption of the intraocular fluid. Usually some atrophy of the ciliary body develops which is also a factor in reducing tension because less aqueous is produced. The operation is indicated in both secondary and absolute glaucoma. Alice R. Deutsch.

Weekers, Roger. A contribution to the study of incomplete glaucoma. *Oph-*

thalmologica, 1943, v. 105, June, pp. 307-317.

If one or the other of the classical symptoms of glaucoma is missing, so called incomplete glaucoma is the result. The monosymptomatic glaucoma which manifests normal tension, normal fields but a distinct pathological cupping is the special study of this paper.

The author observed eight patients affected with this disease. The first patient had the monosymptomatic glaucomatous cupping in one eye only without any other change. Two patients had the same disease in both eyes. Two others had the monosymptomatic glaucomatous cupping in both eyes and an enlargement of the blind spot in one eye. Two others had nerve-fibre scotomas and nasal contraction of the fields with a glaucomatous cupping. The last patient was especially interesting. He had an absolute glaucoma in one eye and a typical monosymptomatic cupping in the other.

This small list of case histories shows the intermediary stages between the monosymptomatic cupping without ocular hypertension and the typical chronic glaucoma with ocular hypertension, field restrictions and visual loss to complete blindness. (6 fields, 1 table, references.)

Alice R. Deutsch.

Westerlund, E. The heredity of congenital hydrophthalmos. *Acta Opth.*, 1944, v. 21, pt. 4, pp. 330-348.

The material is gathered from the records of the Institution for the Blind in Copenhagen, during the period 1881-1942. The total number of children with buphthalmos was 97; in 23 of them it was familial. A detailed analysis of these cases indicates that the mode of heredity in buphthalmos is

recessive. It thus appears, that this form of glaucoma differs genotypically from juvenile and senile glaucoma, which are dominant. The data also reveal that in siblings the course and final outcome of the disease bear the stamp of a familial peculiarity.

CRYSTALLINE LENS

Atkinson, W. S. Corneal section with long bevel and conjunctival flap for cataract extraction. *Arch. of Opth.*, 1946, v. 35, April, pp. 335-345.

The author advocates corneal incision with a long bevel and a conjunctival flap made by keratome and scissors. The long bevel combined with McLean sutures prevents a leaky wound with shallow anterior chamber and also prevents prolapse of the iris. The location in the avascular cornea decreases the incidence of postoperative hemorrhage. The technique of the operation is described in detail. The corneal shelf makes it necessary to deliver the lens by tumbling. Three hundred cases of cataract extraction are reported, divided into groups of 100 each. The last 100 operations were performed according to the technique described. The case reports indicate that the long-beveled corneal section results in superior visual acuity and fewer complications. John C. Long.

Bracken, F. Complications incident to simple intracapsular extraction. *Arch. of Opth.*, 1945, v. 34, Nov.-Dec., pp. 427-430.

Well placed sutures are the best defense against complications with the simple intracapsular operation. The author uses a corneoscleral mattress suture centrally and at least one addi-

tional corneoscleral suture on each side. Rupture of the hyaloid or prolapse of vitreous necessitates a complete iridectomy. Prolapse of the iris is treated as early as possible, either by excision or by replacement and the use of additional sutures. Since he uses corneoscleral sutures the author has found an empty chamber on the morning after surgery in only 0.28 percent of his patients. The technique of delivering the lens is discussed.

John C. Long.

Bracken, F. Instruments for use in operation for cataract. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 430-431.

An anterior chamber irrigator shaped like an iris repositor and attached to a rubber bulb is described. A sharp heavy globe fixation forceps is illustrated. A corneoscleral suture forceps not unlike a miniature Elschnig forceps is described. This forceps has round, needle-sharp teeth and is used to grasp the edge of the cornea or the episclera without pressing on the globe. (3 photographs.)

John C. Long.

Broendstrup, Poul. The function of the retinal periphery in uncorrected unilateral aphakia. *Acta Ophth.*, 1944, v. 21, pt. 4, pp. 303-315.

The tabulated data on the visual fields of 24 persons with unilateral aphakia show that in the aphakic eye there is a moderate narrowing of the visual field amounting to about 10 degrees, which must be attributed to the reduced refractive power of the eye. Such an eye, however, contributes to the total function of the eyes and the desirability of additions to the binocular visual field is an indication for a cataract extraction.

Ray K. Daily.

Chace, R. R. Congenital bilateral subluxation of the lens. *Arch. of*

Ophth., 1945, v. 34, Nov.-Dec., pp. 425-426.

Dislocated lenses in the eyes of a girl, six years of age, are described. The child's maternal grandfather, her mother, and a maternal aunt all had the same condition in both eyes. All were operated upon with varying results; in one of them the operation was followed by glaucoma and later by detachment of the retina.

John C. Long.

Doggart, J. H. Partial cataract in men of military age. *Arch. of Ophth.*, 1946, v. 35, March, pp. 280-290.

Although the word "cataract" is often understood to mean a serious disturbance of the lens in one or both eyes, it has a less sinister significance in ophthalmologic circles, where cataract is defined as a partial or complete decrease in the transparency of the lens. Thus, the term used in its technical sense embraces numerous examples of lenticular opacities which are innocent in that they are either stationary or else advance so slowly as to entail no appreciable handicap within the average span of life.

This survey arose out of the interest shown by the Medical Directorate of the Royal Air Force concerning the relative frequency and practical significance of certain forms of opacities of the lens among men of military age.

In this very readable paper, the author gives the following summary of his investigation.

1. Three hundred men, selected at random, and not complaining of ocular symptoms, were searched for the presence of cataract, so far as that condition is accessible to view through the undilated pupil under the magnification of a loupe.

- 2. Their ages ranged from 19 to 60 years. The average age was 28.2 years. The percentages of air crew members and ground staff were, respectively, 63 and 37.
- 3. The total incidence of cataract was 94.3 percent. Many of the men displayed more than one form of opacity, so that the percentages of the individual types of cataract totaled more than 100. The distribution was as follows:

Type of Cataract	Percent-age
Scattered dots (including dust-like opacities in concentric layers)	93.0
Cataracta centralis pulverulenta	21.7
Coronary cataract	6.0
Anterior axial embryonic cataract	4.0
Dilacerated cataract	1.3
Suture cataract	1.0
Anterior capsular cataract	1.0
Senile cataract	0.3

Doggart concludes that cataract is common and usually harmless and if mentioned at all, the doctor should give a prognosis based on a close study of the type of cataract encountered.

Lawrence, R. D. Temporary cataracts in diabetes. Brit. Jour. Ophth., 1946, v. 30, Feb., p. 78-81.

In two myopic patients who had

been examined at the onset of diabetes and were at that time found to have clear lenses, lenticular opacities appeared 16 days and three days after commencement of a restricted diet and treatment with insulin. They lasted three to five weeks and disappeared entirely. It is suggested that these lens changes were brought on by changes in hydration, both dehydration and rehydration.

Morris Kaplan.

Steffen, R. Posterior pseudo-lenticulus. Klin. M. f. Augenh., 1943, v. 109, March-April, p. 176.

The definitely soft blind eye of a child, two years of age that had an opacity in the posterior portion of the lens, a pea-sized shadow behind it, and whitish strands in the vitreous, was enucleated because of the possible presence of an intraocular tumor. Biomicroscopically loose strands that originated in the region of the disc and spread into the tumor-like mass behind the lens were seen. The retina was partially detached. Histologic sections revealed a cone-shaped protrusion of the posterior surface of the lens that was probably not a congenital malformation but probably a mass of retrolental connective tissue. Apparently an organized inflammatory exudate that compressed the lens peripherally caused the conical bulging of its posterior portion. Clinically the lesion gave the impression of a tumor and might be classified as a pseudo-glioma. (2 photographs, references.)

F. Nelson.

Suellmann, H. The tryptophan content of the lens proteins. Ophthalmologica, 1944, v. 108, Dec., pp. 281-287.

The tryptophan content of the lens proteins in the eyes of calves, cattle, and pigs was determined by the author.

He used various methods (formaldehyde reaction, glyoxal acid reaction) with hydrolysed and non-hydrolysed lens protein and found that tryptophan is 3.5 to 5.3 percent of the total protein. Beta-crystalline contained the most, alpha-crystalline the least tryptophan. The result in cataractous lenses did not vary from those in young lenses. The values obtained by the various methods are critically dealt with and compared with those found by other authors. (Literature.) Max Hirschfelder.

Vetter, J. **Bilateral atypic lens coloboma connected with ectopia.** Klin. M. f. Augenh., 1943, v. 109, March-April, p. 180.

A man 40 years of age who had worn glasses since he was seven years of age had noted diplopia, and later multiple vision, for 19 years. One of the double images often changed its position, especially when he was riding a bicycle on rough pavement. The right lens had been needled previously but was only partially absorbed. Both lenses were small, dislocated toward the nasal side, and had indentations on the temporal side. The zonula fibers were small in number and atypically arranged. Accommodation was almost normal. Iris and choroid were normal. No malformation of the eyes were noted in other members of the family, although two sisters were myopic (7 D. and 20 D.). For the development of atypic coloboma a complete lack of zonula fibers in the colobomatous area is not necessary. Defects in the equatorial region can be caused by a subnormal number of fibers particularly if the normal function of the single fiber is impaired by abnormal arrangement. Coloboma of the lens is probably not a primary inherited malformation but may be secondary to changes in the develop-

ment of the mesodermal tissue in the interior of the eye. (2 pictures, references.) F. Nelson.

Weekers, Roger. **Cataracts in hypocalcemia and their medical treatment.** Ophthalmologica, 1944, v. 107, May-June, pp. 257-281.

After a short review of experimental cataract and a discussion of its pathogenesis and treatment, the author reports nine cases of hypocalcemic cataract in detail. Seven followed strabismus and two were combined with idiopathic tetany. He also mentions the cataracts which develop in hypocalcemia without parathyroid insufficiency, as in nontropical sprue, dinitrophenol poisoning and severe nutritional deficiencies, as well as the similar cataract of myotonic dystrophy.

The morphologic picture of hypocalcemic cataract is characteristic. After a stage of swelling of the lens and an increase in refraction, small radial superficial opacities and colored crystals appear under the posterior and anterior capsule. The nucleus usually loses its transparency before the whole cortex is involved.

The author emphasizes the importance of preventive measures and early diagnosis of the hypocalcemia by checking the calcium content of the blood frequently. Medical treatment is promising, even when signs of visual disturbances are already present. A lenticular myopia may disappear without a trace. The same is true for incipient opacities but when they reach a certain density the process is not reversible.

The drugs used to bring the calcium content of the blood to normal levels are vitamin D, AT 10 which is irradiated dehydrotachisterol, and para-

thyroid extracts. In favorable cases they prevented and retarded the development of cataracts. (References.)

Alice R. Deutch.

Wolff, Eugene. Some aspects of the normal histology of the suspensory ligament of the lens. *Proc. Roy. Soc. Med.*, 1946, v. 39, March, p. 253.

The suspensory ligament of the lens is found to be composed of posterior fibers from the ora that are inserted into the posterior lens capsule, anterior fibers from the valleys between the ciliary processes and the pars plana, auxiliary fibers, and equatorial fibers which decrease in number with age. The "hyaloid" quality of the anterior hyaloid membrane is believed to be due to the hyaloid zonular fibers.

There is still a question as to the origin of the zonular fibers. The author believes that they pass to the internal limiting membrane of the ciliary body, although they may appear to have an interepithelial origin because of the concealing effect of papillary projections of the nonpigmented cells of the ciliary epithelium.

RETINA AND VITREOUS

Arruga, H. Origin and healing of retinal detachment. *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 145.

Since Gonin published his studies it is generally recognized that the formation of a hole or tear in the retina is responsible for its detachment and that a cure can be accomplished by closing and attaching the torn area. Holes can be caused by degenerative or inflammatory changes in the retinal tissue, very frequently where retina and vitreous body are adherent to each other.

Experimental chemical or thermal irritation applied to the surface of the sclera of the eyes of dog, rabbit or cat invariably cause adhesion of the retina to the vitreous that can be seen anatomically. However a retinal detachment does not result from such an irritation since all three membranes, sclera, choroid and retina, are involved in the inflammatory process that follows the irritation. In human eyes a retinal detachment occurs rarely in the presence of a serous choroiditis, but can be more frequently expected when a chorioretinal inflammation predominates in the retina to such a degree that adhesion between choroid and retina does not take place. Shrinkage and retraction of the vitreous body is a physiological process which is progressive from childhood to old age. In the production of retinal holes and subsequent detachment this shrinkage plays a major part, especially where adhesions between retina and vitreous exist. Cystic degenerations in the retinal tissues are often the cause of hole formation. The formation of horseshoe tears in the retinal periphery is influenced by the direction and number of nerve fibers which is diminished toward the periphery. Blood vessels and nerve fibers form the skeleton of the retina. Hole formations in the vicinity of the disc where the layer of nerve fibers is thicker than elsewhere are extremely rare and they are not uncommon in the macula where vessels are absent. When idiopathic retinal detachment occurs only the retina shows pathological changes. The more pronounced the changes are the more serious is the prognosis. Most commonly retinal detachment seems to be produced by a tear in the retina where it is attached to the structure of the vitreous body and where the choroid is nor-

mal. The movements of the vitreous enlarge the holes. Vitreous and eye movements play the most important role in the healing process; it depends upon the absorptive action as well as on the inflammatory reaction of the choroid (adhesive choroiditis). The retina itself plays a passive part only.

Blum, J. D., and Jeanneret, H. **A new anticoagulant in the treatment of retinal venous thrombosis.** *Ophthalmologica*, 1944, v. 108, Sept., pp. 129-136.

Dicoumarin was originally a product of sweet clover but was synthesized in 1941 and has been in use since 1942. It increases coagulation time by retarding the formation of prothrombin, although the variations in coagulation time in prothrombin time are not proportionate.

The dosage varies between one-half and four milligrams per Kilogram of bodyweight per day. Its action is slow and its anticoagulant effect becomes manifest after 48 to 72 hours. After that time the prothrombin time must be checked regularly. A prothrombin time of 30 to 45 seconds is considered

to be within safe limits, 60 to 80 seconds is a danger sign.

Contraindications in the use of Dicoumarin are malignant vascular sclerosis, arterial hypertension, and increased capillary permeability.

Its advantages, if compared with heparin, are the reasonable price, the administration by mouth, and its prolonged action.

Seven case histories are reported in detail. Three patients had complete thrombosis and four had thrombosis of a branch of the retinal vein. The practical value of the combined use of heparin and dicoumarin is outlined. (2 figures, references.)

Casanovas, Jose. **Grouped pigmentation of the retina.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Feb., pp. 129-132.

The author reports a case of a rare congenital anomaly described by Niels Hoeg under this name, by Leber under the name of nevoid pigmentation of the retina, and by Kraupa as melanosis of the retina. The anomaly consists of a grouped formation of round or polygonal dark areas, located behind the retinal vessels in some segment of the retinal periphery. It is formed in the early stages of ocular development, and is due to an irregular distribution of the cells in the retinal pigment layer. Its clinical significance lies in the possibility of its confusion with hemorrhages or pathologic pigmentation. (2 colored illustrations.) Ray K. Daily.

Cridland, Nigel. *Neuroretinitis of unknown origin*. Proc. Roy. Soc. Med., 1946, v. 39, March, p. 245.

A man, 24 years of age, suffered a progressive loss of the peripheral field to five degrees, in a period of six months. The visual acuity remained 6/5, and the fundus appeared normal. Three months later the field was smaller (three degrees), and a trephine operation was performed to aid retinal circulation. There was no further change in the field or visual acuity. The fundus showed some fine pigment deposits along the inferior nasal vein and equivocal retinal edema. After three years there is no further change, except for fine diffuse areas of chorioretinitis. The only explanation offered was that the initial lesion was a superficial widespread choroiditis.

Benjamin Milder.

Granström, K. O. *Retinal hole observed fifteen months before detachment of the retina*. Acta Ophth., 1943, v. 21, pt. 3, pp. 204-209.

In the emmetropic eye of a woman, 54 years of age, a typical retinal hole was observed fifteen months before retinal detachment occurred. A review of the literature shows a divergence of opinion as to the necessity of surgical treatment for such eyes. The occurrence of detachment in this patient leads to the conclusion that a prophylactic operation should have been performed.

A case of eclipse blindness that appeared a few hours after exposure is described. It was characterized by diminished vision, a positive scotoma, and an obvious hole in the macula. The damage apparently was permanent. (Illustration.) Morris Kaplan.

Louis-Bar, D., and Pirot, G. *Spastic paraplegia combined with degeneration of the macula in two brothers*. Ophthalmologica, 1945, v. 109, Jan., pp. 32-43.

In presenting the unusual occurrence of several degenerative diseases in two brothers, the authors take the opportunity to discuss the interesting problem of the heredity of pathologic lesions and their simultaneous occurrence in one individual. The brothers had a degeneration of the macula associated with a spastic paraplegia of the Strümpel type. In one of them it was the infantile form and in the other the adult form. In one of them the spastic paraplegia was accompanied by an amyotrophic spinal lesion. A third member of the family had an atypical spastic paraplegia. The investigation of the heredity of the abnormalities in the family was necessarily incomplete.

The authors believe that the degenerations of the macula in their patients were of the type described by Franceschetti in patients with Freidreich's ataxia. No similarly afflicted family has been described. Alice R. Deutsch.

Ortin, G. L. **Retinitis pigmentosa.** Arch. de la Soc. Oft. Hisp.-Amer., v. 5, Feb., pp. 92-111.

The importance of consanguinity and the futility of therapy are the features emphasized. After surveying briefly the known facts in the pathogenesis of the disease Ortin concludes that the primary lesion is a destruction of the neuro-epithelium. Reference is made to McDonald's and Adler's study on the relation of pituitary disease to retinitis pigmentosa, and their opinion denying the influence of a pituitary hormone is accepted. The therapeutic procedures advocated are mentioned with scepticism in their efficacy. In the author's personal experience injections of acetylcholin and atropin intravitreally and retrobulbarly were without effect. Effective prophylaxis through genetic regulation and elimination of consanguinous marriages, is strongly urged. (8 fundus photographs, 32 visual fields.) Ray K. Daily.

Panneton, P. **A curious lesion of the fundus.** Arch. d'Ophth., 1945, v. 5, no. 3, p. 328.

The author describes the eyes of a man, 44 years of age, with vision reduced to 0.2 in the right eye as the result of infectious keratitis that had occurred some two months before examination. The left eye was externally normal and had a vision of 0.9. In this eye, however, there was a whitish mass at the upper temporal margin of the nervehead about half the size of the disc in area. The mass was elevated

about three diopters and the borders were sharp. The color was a grayish white with a suggestion of cholesterin crystals. The mass obscured the upper temporal vessels. Otherwise the fundus was completely normal. The author discusses the various etiological possibilities, particularly gumma, tuberculoma, and tumor. He suggests that the mass may be a conglomeration of cholesterin crystals.

Phillips Thygeson.

Pinkerton, O. D. **Angioma of the retina.** Amer. Jour. Ophth., 1946, v. 29, June, pp. 711-712. (3 figures.)

Ploman, K. G. **Treatment of thrombosis of the retinal veins with heparin.** Acta Ophth., 1943, v. 21, pt. 3, pp. 190-203.

This report is based on 41 cases of thrombosis of the central retinal veins and 40 cases of thrombosis of tributary veins. The tabulated data show that the best results were obtained in younger patients and in those in whom therapy was instituted early. The patients who were not benefited had hemorrhages into the vitreous or the retina. Secondary glaucoma and central choroiditis were causes of failure in some patients. When the thrombosis occurred in a branch of the vein, improvement was noted in the eye of almost half of the patients. In practically every case sinuous veins, uneven in calibre, and with thickened walls were left in the affected area. Similar changes took place in the concomitant artery. It is useless to treat patients with massive hemorrhages that obscure the papilla and the macula, and those who have increased tension. Impairment of visual acuity should not be the deciding factor, because it sometimes improves rapidly during the

course of treatment. If the papilla is visible, and the hemorrhages not too extensive, heparin should be tried.

Rasmussen, Knud. Retinoblastoma in a man forty-eight years of age. *Acta Ophth.*, 1943, v. 24, pt. 3, pp. 210-213.

To the small number of reported cases of this tumor in adults, the author adds one. The patient was treated for two years for keratitis, iritis, and secondary glaucoma. When light perception was gone, the eye was finally enucleated, and was found to contain a retinoblastoma. (1 illustration.)

Ray K. Daily.

Redslob, E., and Koutseff, A. Postpartum retinopathy. *Ann. d'Ocul.*, 1945, v. 178, Oct., pp. 425-440.

During pregnancy ovarian hormones, especially folliculin, and placental hormones greatly increase the activity of the entire endocrine mechanism, especially the pituitary which physically, by swelling, produces bi-temporal field contractions and chemically by the increased hormone production, especially of oxytocin, partly causes the uterine contractions of labor. Among the abnormalities of this complexly balanced process are quantitative and qualitative changes in the vaso-pressor system which produce hypertension in the predisposed. The stages are angiospasm, angiosclerosis, exudation with or without necrosis, and other complications. The tissues most frequently involved are the kidneys, the liver and the retina. In severe forms, eclampsia with retinopathy results. The tendency to angiospasm and there-

fore hypertension in pregnancy is aggravated by vaso-pressor hormones such as vasopressine, adrenalin, and folliculin. Generally speaking, the severity of the retinopathy is proportionate to the vascular hypertension rather than to the kidney involvement. Two illustrative cases are presented, both apparently with hereditary lues. In the first patient eclampsia with bilateral retinal exudation and detachment occurred several hours after a normal labor. A subsequent pregnancy was terminated to save the life of the patient. The second patient also developed eclampsia and bilateral retinal exudation and detachment after she had been delivered of an apparently normal child during the seventh month of pregnancy. Three months later the eye and vision were normal. (15 references.)

Chas. A. Bahn.

Rosengren, B., and Stenstrom, S. Thirty cases of thrombosis of the retinal vein treated with heparin. *Acta Ophth.*, 1942, v. 20, pt. 2., pp. 145-152.

The conclusions are based on a detailed analysis of 30 cases. After 250-375 milligrams of heparin had been administered daily for an average of 10 days, visual acuity had improved in 21 patients, had deteriorated in five, and remained unchanged in four. The average visual acuity before heparin therapy was .239; at the end of heparin therapy, it rose to .375. After the administration of heparin was discontinued, there was a slight loss. These findings support the belief that in many cases heparin therapy leads to improvement, which is later partially lost.

Ray K. Daily.

Scheie, H. G., and Freeman, N. E. Vascular disease associated with angioid streaks of the retina and pseu-

doxanthoma elasticum. Arch. of Ophth., 1946, v. 35, March, pp. 241-250.

During the past two years angioid streaks of the retina were seen in three patients, in two of whom pseudoxanthoma elasticum was also present. In these two patients severe vascular disturbance was found in all the extremities. No mention of a relationship of these three conditions has been found in the available literature and whereas the association is probably significant, the cases are being reported.

Pseudoxanthoma elasticum is a degenerative disease of the skin. The co-existence of osteitis deformans and angioid streaks of the retina is also noteworthy.

Angioid streaks of the retina are rather rare. The retinal picture is characteristic. It consists of pigmented streaks, radiating spokelike from a similarly pigmented ring which encircles the disk. This ring may be complete or incomplete and may be formed by a single pigmented line around the disk, or it may be made up of several interlacing lines of pigment. It may encircle the disk closely, with only a small band of retina intervening, or the ring may be 0.5 d.d. or more away. The borders are serrated.

Pseudoxanthoma elasticum is an abnormality of the skin that is made manifest by yellowish patches, that vary in size from that of a pinhead to that of a pea, with roughening of the skin much like the striae atrophicae of pregnancy.

Obstruction of peripheral blood vessels or serious circulatory disturbance has not previously been reported.

The angioid streaks of the retina, pseudoxanthoma elasticum, and vascular disturbance reported in two patients were believed to be a manifesta-

tion of a general degeneration of elastic tissue throughout the body and will probably be found to occur together not infrequently when such cases are studied with this in mind.

Vail, Derrick. The scleral-resection (eyeball-shortening) operation. Amer. Jour. Ophth., 1946, v. 29, July, pp. 785-799. (1 color plate, 7 figures, references.)

Van Manen, J. G. Congenital sickle-shaped retinal detachment and associated congenital anomalies. Ophthalmologica, 1944, v. 107, March-April, pp. 121-148.

Two congenital anomalies of the fundus were seen by the author in the Netherlands-Indies where congenital anomalies of the eyes are not rare among the natives and are favored by intermarriage of members of the same tribe.

In a boy 16 years of age whose left eye only was affected, the optic disk was pale and a grayish transparent strand extended towards the periphery in the horizontal meridian. Another but shorter and less transparent strand surrounded the region of the macula like a dense sheath. It extended straight into the vitrous perpendicular to the retina, and with the other strand formed a fanshaped veil which reached the ora serrata. In the region of the posterior pole there were spots of fine pigment and coarse dots with many glittering points in the retina, which was scarcely pigmented at all elsewhere. The lens was clear. The eye was emmetropic and vision was reduced to the ability to count fingers at two meters.

The second case occurred in a boy, six years of age. He had a typical sickle-shaped congenital retinal de-

tachment in the inferior temporal quadrant that was more pronounced in the left eye where it was associated with an anomaly of the retinal artery. Nystagmus was present and his vision was very poor.

The author also reviews ten cases of this eye affection which were reported under different names and discusses the pertinent pathologic studies.

To explain the probable genesis of sickle-shaped, congenital retinal detachment and allied anomalies a detailed embryologic study is added to this paper. Superficial branches of the hyaloid artery which normally are obliterated in the 40 millimeter stage retain their delicate fibrillary connection with the retina and by their persistence nourish and increase the growth of the mesoderm at the lens equator. The latter adheres to the adjoining retina. The growing eyeball stretches the persistent vessels which are covered by the congenital neuroglia of Bergmeister and by the mesoderm at the posterior lens capsule. The retina, fixed to the vessels, must give way and form a fold. (6 figures, references)

Weber, Ernst. Biomicroscopic investigation of the anterior limitation of the vitreous and its connection with the lens. *Klin. M. f. Augenh.*, 1943, v. 109, March-April, p. 169.

In continuation of a previous article concerning the free layer of the vitreous lamella and its delimitation from the plicata, a lenticular membrane of the vitreous lamella is described which is often not visible but can become manifest in senile eyes and after post-traumatic and inflammatory processes. The free vitreous layer plus the lens lamella form the anterior limit of the vitreous which is visible in slitlamp

illumination. The plicata plays no important part as an anterior limiting membrane. Characteristic for the detachment of the lens membrane of the vitreous lamella are the following: (1) an optically empty space behind the lens, (2) the usual jerky movements are small or absent (in contrast to the plicata), (3) vivid iridescence, (4) the membrane is not folded like the plicata but is stretched tightly, (5) occasionally, especially after trauma, fine parallel striation is present, (6) usually it can be isolated from the rear surface of the lens only in very narrow optical sections. Detachment of the lens lamella can be proved by the visible continuation of the plicata, towards the vitreous lamella, direct transition into the free layer of the vitreous lamella, and by apparent detachment of the hyaloid canal at its insertion at the rear of the lens. Each one of these three symptoms is sufficient for the diagnosis of detachment of the lens lamella. (3 color plates, 4 drawings, references.)

Weekers, Roger. The impairment of the circulation and the function of the retina in the post-concussional syndrome. *Ophthalmologica*, 1944, v. 108, Oct.-Nov., pp. 169-186.

The post-concussional syndrome has been considered a manifestation of a neurosis or of simulation. The most important result of this study is the discovery of a new sign for its diagnosis, namely, the extension and abnormal increase of the angioscotomas. This observation also has a pathologic interest because it stresses the importance of circulatory changes. It is of practical interest because it helps to verify the diagnosis and to outline the seriousness of the affection, its course and prognosis.

The author describes the anatomy of the retinal and choroidal circulation and the methods for examination of the retinal function. The technique of the angioscotometry, its variations and the interpretations of its findings are discussed in detail as are the changes in the adaptation curves and in the color sense.

The author found that narrowing of the central and peripheral isopters can arise without excessive fatigue and without neurosis. This results from an extension of the vessel scotomas, as does the decrease in the visual acuity and retinal asthenopy. Under the technical conditions at hand, the dark adaptation only was impaired in several afflicted patients who also showed considerable contraction of the fields and impaired visual acuity. There was no change in the color sense other than a concentric contraction of the peripheral isopters for colors. The enlargement of the angioscotomas may arise from a change in the conduction of the neurons and synapses of the retina that is caused by disturbances of the circulation in the retinal vessels.

The study of the functional deficiency of the retina permits an approximate estimation of the severity of the post-concussional syndrome. In this respect three categories might be distinguished: grade 1, increased angioscotoma only, capable of improvement or complete recovery; grade 2, contraction of the middle and peripheral isopters, always accompanied by serious general symptoms and a slow recovery, grade 3, the impairment of the retinal circulation is so severe that not only the fields but also the visual acuity is very much impaired. The prognosis is grave. (2 field charts, references)

Weekers, R., and Humblet, M. **Physiological angioscotoma.** *Ophthalmologica*, 1945, v. 110, July-Aug., pp. 43-59.

The authors describe a new and especially exact method for plotting physiological angioscotomas. They discuss variations in angioscotomas, their theoretical significance, and their importance in health and disease. They correlate their findings with the appearance of the retina in ophthalmoscopy and in fundus photographs. The vascular origin of the behavior and etiology of these physiologic restrictions in the fields is clearly demonstrated. They use Bjerrum's tangent screen made of black wool that is free from reflections. The fixation point is a hole illuminated from behind by a red light. The tangent screen is uniformly illuminated by two tubes whose light is regulated by the interposition of a diaphragm. Three to five lux is the most desirable illumination. The testmarks are of a mat white and one to 15 millimeters in diameter.

In experimental anoxemia, in glaucoma, and after cerebral concussion, disturbances in the visual fields were found which resemble angioscotomas but are much broader and denser. Whenever this occurs the physiological angioscotoma disappears in the much larger pathological scotoma. (6 figures, references.) Alice R. Deutsch.

Zorab, E. C. **Solar eclipse—burn of macula.** *Brit. Jour. Ophth.*, 1946, v. 30, Feb., p. 82-84.

A soldier complained of reduced vision in the right eye four days after watching a partial eclipse of the sun intently without adequate protection. He complained of reduced vision in the left eye and the constant presence of a shadow. The shadow was of the

exact shape of the uneclipsed portion of the sun. This remained for 20 days and improved slightly. In each macula there was no light reflex and a dark red spot in the center about 0.25 mm. in diameter with a very pale arc surrounding it about 0.75 mm. in diameter.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Antoine, R., Legroux, R., and Stricker, P. A case of severe quinine amblyopia. *Arch. d'Ophth.*, 1945, v. 5, no. 3, p. 349.

A case of toxic amblyopia following the ingestion of 6.0 gm. of quinine given for malaria is reported. Vasodilators were employed immediately but when the patient was first seen by the authors, several weeks later, there was complete mydriasis with absence of pupillary reflexes and of light perception. Injections of acetylcholine were given and the drug was applied to the sphenopalatine ganglia. There was improvement within 48 hours; light perception first returned in the temporal fields. After six days light projection was recognized everywhere except in the nasal fields and the visual acuity was 0.7 right eye and 0.5 in the left. Because the visual fields remained markedly constricted, the superior cervical sympathetic ganglia were infiltrated with procaine daily; definite improvement followed. Several months later the patient had a recurrence of malaria which was treated with quina-crine over a ten-day period. Although visual acuity remained unchanged after this treatment, there was marked contraction of the fields of the left eye. This contraction disappeared, however, after a single blocking of the superior cervical sympathetic ganglion.

The authors consider this case to be further proof of the role of vasoconstriction in the pathogenesis of quinine amblyopia. They discuss in some detail the anatomy of the cervical sympathetic chain and conclude that almost all vasodilator fibres pass by way of the superior cervical ganglion.

Phillips Thygeson.

Bordier, F. Inquiry into ocular intoxication caused by tobacco called "green." *Ann. d'Ocul.*, 1945, v. 178, Sept., pp. 370-376.

A farmer, 74 years of age, experienced amblyopia, central scotomata, internal ophthalmoplegia, slight myopia, and retinal arterial hypertension. These manifestations were apparently caused by smoking daily approximately 30 cigarettes of his home grown, home cured tobacco. After changing to another tobacco, possibly smoking less, and taking vitamin B, his symptoms disappeared. The author concludes that the home grown tobacco contained different toxic substances which affected the retinal cones and the contractility of the unstriated muscular tissue contained in the arterioles of the iris and ciliary muscle.

Falomir, Eduardo W. The problem of optic neuritis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, March, pp. 169-172.

A brief discussion of the differential diagnosis of optic neuritis and papilledema is presented.

J. Wesley McKinney.

Porsaa, Kaj. Papilloedema in iridocyclitis. *Acta Ophth.*, 1944, v. 21, pt. 4, pp. 316-329.

Three cases are reported, one chronic and two acute. The edema in-

volved the optic nerve, blurring its margins, and extended into the retina, toward the fovea. There were a few exudates and hemorrhages in the edematous area, the retinal veins were engorged, and there were vitreous opacities. The ocular tension was normal. The vision was not impaired by this process and recovery was complete. Porsaa reviews the literature, which supports the theory that this is a toxic collateral edema, with stasis in the retinal veins, due to the inflammatory process in the anterior ocular segment.

EYEBALL AND ORBIT

Babel, J., and Valerio, M. **Amputation-neuroma of the orbit.** *Ophthalmologica*, 1945, v. 109, June, pp. 317-323.

The authors describe two cases of amputation-neuroma in the orbit.

The eyeball of a man, 40 years of age, was enucleated because of recurrent inflammations which followed a perforating injury. Severe pain in the socket started several years later, after an apparently unimportant orbital trauma. The pathologic examination after surgical exploration showed a growth the size of a cherry stone, which was not encapsulated. It was a typical amputation-neuroma with chronic inflammatory cellular infiltration. In the stump of the optic nerve

there was a small granuloma with giant cells.

In the second patient the eyeball was removed because of complications after trachoma. Here a real tumor was not present, but a large number of myelin free nerve fibers in irregular arrangement. The ends of the severed nerves were visible and also many regenerated nerve fibres, but there were no inflammatory changes. There had been no pain before the operation.

The phenomenon of nerve regeneration in the orbit has never been described before though it does not seem to be rare. The ciliary nerves seem to be the origin of the tumor. It might be the cause of considerable pain after enucleation, especially if inflammatory foci should develop in the stump. (5 figures, references.)

Alice R. Deutsch.

Bendor-Samuel, J. E. L. **A case of siderosis bulbi.** *Brit. Jour. Ophth.*, 1946, v. 30, Feb., pp. 85-88.

A soldier complained of pain in a blind eye that had had penetrating trauma a year before. A traumatic cataract and siderosis bulbi were present. A foreign body was removed by means of a magnet through a posterior incision in the sclera. The cataract was removed. After a needling the vision was corrected to 6/12 though the pigment deposits remained.

Morris Kaplan.

Chavany, J. A. **Orbito-temporal osteoma with exophthalmos in syphilis.** *Presse Medicale*, 1945, No. 51, Dec. 22, p. 702.

Chavany reports two cases of exophthalmos in syphilitic patients. In the first patient the exophthalmos was unilateral, of six years duration, and caused by a painless bony mass in the

temporal part of the orbit. Ocular function was normal. The diagnosis of osteoma was confirmed by X-ray examination. All other physical and laboratory findings were negative except for positive Bordet-Wassermann reactions. A diagnosis of syphilis was confirmed by a history of repeated miscarriages. Intensive antisyphilitic therapy with bismuth and potassium iodide failed to influence the eye lesion but did render the serologic reaction negative.

The second patient presented a hard, painless tumor of the left orbito-temporal margin with marked exophthalmos. Radiography showed a condensation of the bone in this area. Symptoms were of three years duration, the onset of the lesions was insidious, and the progression was slow. Physical findings were otherwise normal except for an Argyll-Robertson pupil. Serologic reactions of the blood and spinal fluid were negative but antisyphilitic therapy seemed to be indicated nevertheless.

The author believes that antisyphilitic therapy must be tried but if the lesions progress under therapy the possibility of osseous syphilis is eliminated and surgery is indicated.

Phillips Thygeson.

Gronvall, Herman. A case of chloroma of the orbit with fundus changes. *Acta Ophth.*, 1944, v. 21, pt. 4, pp. 260-266.

The initial symptom of a fatal case of chloroma in a girl five years of age, was a swelling in the right orbit. The child had a displacement of the right eyeball downward and nasally, and ptosis of the lid. The fundus was pale, the vessels bright, wide, and tortuous. The disk margins were obscured and the temporal portion of the disk was pale and surrounded by fine hemor-

rhages. There was a large hemorrhage in the macula and fine hemorrhages in the periphery. The fundus of the left eye presented a similar picture without a macular hemorrhage. The diagnosis was made from the blood picture, and confirmed at autopsy. This disease should be considered in the differential diagnosis of orbital tumors in children. (1 illustration.) Ray D. Daily.

Hinterleitner, K. Tuberculosis of the orbital tissue. *Ophthalmologica*, 1944, v. 108, Oct.-Nov., pp. 210-216.

The author observed two cases of tuberculosis of the orbital tissue. The first patient, a woman 57 years of age, presented a swelling of the lower eye lid, moderate exophthalmus, a hard, indolent mass at the lower orbital margin that spread towards the depth of the orbit and negative X-ray plates. Tuberculin reaction was positive. A biopsy demonstrated tuberculous granulation tissue with giant cells. Treatment by means of Xrays and arsenic lead to improvement. The second patient, a 12-year-old girl, had a slowly growing small mass under the upper orbital rim. The mass was extirpated and found to consist of infiltrates of lymphocytes and epithelioid cells. There was complete recovery without recurrence. The author discusses the literature on primary tuberculosis of the orbit. (Bibliography).

MacKenzie, C. M. Choice of grafts for orbital reconstruction. *Amer. Jour. Ophth.*, 1946, v. 29, July, pp. 867-869. (7 figures, references.)

Mann, Ida. Exophthalmic ophthalmoplegia and its relation to thyrotoxicosis. *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 654-673. (36 figures, 1 table, references.)

Muzzio, J. C. **Orbital complications of sinusitis.** *La Semana Méd.*, 1946, v. 53, April 4, pp. 593-604.

The author relates nine cases. In each case the causal factor was a cold or influenza. Polysinusitis predominated over monosinusitis in the production of orbital complications. Although maxillary involvement is the most frequent form of sinusitis, it and sphenoidal localization produce the smallest number of orbital complications. Acute sinusitis, or reactivation of the chronic condition, will in most cases be adequately treated by medical procedures. If surgical care is necessary, this should at first be limited to drainage of the infected sinus or sinuses. The radical treatment may be postponed for weeks or months after the acute phase has receded or disappeared. (Bibliography.)

W. H. Crisp.

Offret, M. C., and Offret, G. **Malignant exophthalmos in Basedow's disease. Etiologic and therapeutic study.** *Arch. d'Ophth.*, 1945, v. 5, no. 4, p. 429.

The authors define malignant exophthalmos as any exophthalmos, pre- or post-operative, accompanied by a lowering of vision. This drop in visual acuity may arise from such different sources as corneal ulceration or an optic nerve atrophy but the amount of visual loss may be considered a measure of the malignancy of the exophthalmos. Unlike certain American authors they do not consider malignant only those cases in which the exophthalmos persists or is aggravated after thyroidectomy.

According to the authors the frequency of malignant exophthalmos has varied in the different series reported since 1840 when Basedow first noted the progressive character of the exophthalmos and consequent ulceration in

certain cases. At least 100 cases have been reported in the literature; Sattler in 1909 summarized the data on 63 and the present authors did the same for 37. They discuss in turn the pathogenesis, the clinical aspects, the differential diagnosis, the pathologic anatomy, and the treatment of the condition and conclude that malignant exophthalmos in the course of Basedow's disease is an important cause of blindness and that it occurs most often after improvement or healing of the thyrotoxicosis. They consider that diffuse edema of the orbital tissues with hypertrophy of the extraocular muscles is the principal anatomic lesion and refer to the experimental studies which indicate that thyroidectomy plus overaction of the anterior lobe of the pituitary are significant factors. They note that exceptionally malignant exophthalmos can occur as a specific disease in the absence of any thyroid disturbance. They conclude that medical, particularly hormonal, therapy offers the greatest ultimate hope but that at the present time surgical decompression of the orbit, by various methods, is the most important treatment.

Peter, A. L. **Oxycephaly associated with Klippel-Feil syndrome and other skeletal defects.** *Amer. Jour. Ophth.*, 1946, v. 29, June, pp. 694-698. (See Section 17, Systemic diseases and parasites.)

Pyeton, W. T., and Simmons, D. R. **Neurofibromatosis with defect in wall of orbit. Report of five cases.** *Arch. Neurol. and Psychiat.*, 1946, v. 55, March, p. 248.

Recklinghausen's disease, neurofibromatosis, is a congenital defect which may affect any part of the body.

It is probably the result of defective germ plasm. Because of the mesenchymal origin of the lesions, it is understandable that many bony defects are associated with the disease. The skull is often the site of changes, not all of which are associated with contiguous tumors.

In the literature 20 cases are reported showing defects in the orbital roof, that allow free communication between the orbit and the intracranial cavity. Five such cases are reported by the authors. All were characterized by exophthalmos, usually of the pulsating type. Some of the patients had skin lesions of neurofibromatosis. Although the diagnosis was not immediately apparent in each case, it was possible to demonstrate roentgenographically an enlargement of the orbit and a defect in the roof. The exophthalmos may be due to (1) orbital neurofibromatosis or a coexisting orbital tumor, or (2) brain tissue in the orbit, producing the pulsations. The proper treatment in the latter instance is repair of the roof of the orbit by transfrontal craniotomy.

Šmejkal, V. **Injections of 90-percent alcohol in ophthalmology.** *Praktický Lékař*, 1946, v. 26, Feb. 5, pp. 81-82.

Excellent results were obtained with retrobulbar injections of 90-percent ethyl alcohol in 62 patients, under local anesthesia; 0.5 to 1.0 c.c. was injected in patients with spastic entropion or a painful blind eye. O. Felsenfeld.

EYELIDS AND LACRIMAL APPARATUS

Arruga, H. **Penicillin in a grave case of congenital dacryocystitis.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Feb., pp. 133-134.

A congenital dacryocystitis with fistula formation, remained without improvement for five days under irrigation, protein injections, and sulfonamides. It cleared up within the next eight days, under irrigation with penicillin. The fistula closed, the lacrimal passages were open, and the epiphora subsided. Ray K. Daily.

Berke, R. N. **Blepharoptosis.** *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 434-450.

This is a detailed review of the literature on the etiology, incidence, anatomy, and surgical treatment of ptosis of the upper lid and related defects. An outline is given for the pre-operative study of this condition. The eighty or more operations for ptosis may be divided into three groups: (1) Suspension of the upper lid from the brow, thus utilizing the action of the frontalis muscle for lifting the lid. (2) Attachment of the upper lid to the superior rectus, thereby replacing the action of the levator by the lifting power of the superior rectus. (3) Enhancement of the normal action of the levator by advancing, tucking, or resecting this muscle.

None of these procedures are entirely satisfactory in all cases. As a general rule, resection of the levator palpebrae muscle is the operation of choice when this muscle is not paralyzed. Next in the order of preference is one of the operations which utilizes the superior rectus muscle. If this muscle is weak, the frontalis type of operation is indicated. John C. Long.

Crookes, G. P. **Traumatic blepharospasm as an isolated symptom.** *Brit. M. J.* 1946, no. 4447, March 30, p. 486.

The author reports a case of traumatic reflex blepharospasm of five day

duration in a girl 13 years of age. Blepharospasm was the only finding. Two c.c. of procaine solution was injected at the neck of the mandible and within five minutes all findings disappeared completely. I. E. Gaynon.

Dupuy-Dutemps, P. Obliteration of the lacrimal passages and its treatment. *Ann. d'Ocul.*, 1945, v. 178, June, pp. 242-254.

In burns and injuries of the canaliculi with slight ectropion, canalicular slitting with excision of the conjunctival wall may suffice. In more severe ectropion, autoplasties such as the Kuhnt-Zymanowski procedure are more efficient. In slight infections, especially those that follow blepharoconjunctivitis, dilatation and irrigation may be sufficient. The use of large probes or other methods which traumatize the sac should be avoided because of ultimate cicatrization. In congenital obstruction of the sac the smallest probe will frequently restore potency by puncturing the unabsorbed nasolacrimal membrane. Severe infections in children should be reduced to a minimum. If necessary, the sac should be excised, but if it is at all possible, the operation should be postponed until about the twelfth year of life when a dacryorhinostomy can be performed. In traumatic strictures of all sorts this operation is the procedure of choice. Sac infection secondary to nasal infection is rare. In infective dacryocystitis complicated by corneal ulcer, extirpation of the sac is indicated because convalescence is more rapid. Cauterization of the sac by physical or chemical methods is not advised. Dacryorhinostomy is preferred because of its greater success and permanency. It is contraindicated in the aged and if the nasal mucosa is atrophic or

badly diseased. Physiologic permeability is established in four to six weeks. Chas. A. Bahn.

Frouchtman, R. The etiopathogenesis and treatment of blepharitis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, March, pp. 173-184.

The study of a group of fifteen patients who had blepharitis leads the author to believe that the affection is a dermatosis localized in the lid borders. The development of the condition is subject to the many factors which contribute to the appearance of the allergic dermapathy. Constitutional predisposition, focal sepsis, the elimination of which is not always followed by cure, digestive factors, endocrine disturbances; hepatic insufficiency, affections of the anterior segment of the eye, mechanical physical and chemical agents, and sensitization to microbes which normally inhabit the skin are factors which the author considers. Sensitization to saprophytic bacteria of the air was shown to be causative in two patients who were cured by the injection of extracts of sarcinae. Several of these factors may be combined to give a complicated etiopathogenesis in any particular case of blepharitis.

J. Wesley McKinney.

Gauffre, R. An operation for congenital coloboma of the upper lid. *Arch. d'Ophth.*, 1945, v. 5, no. 3, p. 342.

The author reviews the operative indications in congenital coloboma of the upper lid and stresses that early operation may be mandatory to protect the exposed cornea. He states that the tissues of infants are particularly fragile and do not react well to traction or constriction and do not hold sutures well. In an effort to avoid complications arising from this tissue fragility

he employed akinesis with a solution of 40 percent alcohol to eliminate lid spasm and used warm saline dressings, changed every two hours, to minimize tissue swelling. Phillips Thygeson.

Gronvall, Herman. **On argyrosis and concretion in the lacrimal sac.** *Acta Ophth.*, 1944, v. 21, pt. 4, pp. 247-259.

A review of the literature is followed by a detailed report of two cases. In one of the patients a hard, black dacryolite was found. The interesting feature was the difference in the histologic picture of the sacs. In this first case, the pigment was found on the elastic fibres and in the inflammatory tissue. In the second case, the pigment was deposited in the basal membrane of the epithelium and in the star-shaped connective tissue underneath. Ultra-violet spectral analysis of the dacryolite revealed the following constituents: Ca, Ag, Mg, Fe, P, Al, Cu, Na, and possibly Si. (4 illustrations.) Ray K. Daily.

Iribas, Gregorio. **Adrenalin in narrowing of the lacrimal passageways.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, March, pp. 206-207.

The author cites the advantage of the use of adrenalin to shrink the mucosa before probing for stenosis of the nasolacrimal duct.

J. Wesley McKinney.

Lutman, F. C., and Favata, B. V. **Keratoconjunctivitis sicca and buccoglossopharyngitis sicca with enlargement of parotid glands.** *Arch. of Ophth.*, 1946, v. 35, March, pp. 227-240.

Sjögren, in 1933, described a chronic disorder characterized by reduction in the secretions of the lacrimal and salivary glands with accompanying keratoconjunctivitis sicca, and dryness of

the mucous membranes of the mouth and the upper respiratory system. A persistent enlargement of the parotid glands sometimes occurred. The several publications of Sjögren on this subject have established the condition as a syndrome that now bears his name.

The numerous complications in the development of this disease do not occur in every patient, but the high incidence of each warrants the belief that they involve many of the body's systems, and that the ocular manifestations are but a part. In the presence of a chronic inflammation of the lacrimal gland, the forms of local treatment that have been suggested must be considered of no more than palliative value.

Two cases of Sjögren's syndrome are reported in detail. The microscopic pathologic changes in a lacrimal gland and the parotid glands in one case are described. Some of the complications and possible causes of this disease are discussed. A clinical resemblance to advanced chronic ariboflavinosis is noted. R. W. Danielson.

Lyle, T. K., Cross, A. G., Simpson, J. F. **Dacryo-cysto-rhinostomy.** *Brit. Jour. Ophth.*, 1946, v. 30, Feb., pp. 102-119.

Fifty cases of dacryo-cysto-rhinostomy are analysed and the results found to be uniformly satisfactory. The operation, which is much like the Toti-Moser procedure except that the skin incision is placed more anteriorly, is described in detail with the help of good diagrams. Lipiodol injection for X-ray study and a careful nasal examination are always done before surgery. General anesthesia is preferred. The authors believe that a simple excision of the sac is entirely insufficient. The surgical cooperation of an ophthalmol-

ogist and a rhinologist is strongly urged. The only contraindications to the operation are definite absence of the sac and irreparable obstruction of the lower canaliculus. (7 illustrations).

Morris Kaplan.

Niemeyer, Waldemar. Autoplastic dacryorhinostomy. *Arquivos Brasileiros de Oft.*, 1945, v. 8, Dec., pp. 181-185.

The technique described was first published by the author at the second Argentina Congress of Ophthalmology in 1940.

After the usual preparation, the nasal bone is trephined, the opening being beveled so as to make it larger toward the nasal fossa. With a Deschamps hook or other instrument, a silk thread number 2 or 3, more or less 20 to 25 cm. long, is passed through the slit lower canaliculus and the bony gap, and is brought out through the corresponding nasal passage. A flap of labial or buccal mucosa is prepared, measuring (after dissecting away the fatty tissue) 12 to 14 mm. in length by 12 mm. at the base and 10 mm. at the upper side (slightly trapezoid form).

With three stitches of fine chromic catgut, this flap is sutured in its length to form a sort of sleeve, with the raw surface outside. The silk thread which served as a guide is pushed into the nasal extremity of the tube so as to hold the flap in its definite position, the proximal end being united to the distal extremity of the canaliculus. A small chromic catgut suture is sufficient to fix the proximal extremity of the new canal to the distal extremity of the canaliculus. Care must be taken to make the periosteal resection larger than the bony opening; and also to avoid leaving a bony fragment in the

canal. The tube of mucosa should not be longer than necessary for good union between the end of the canaliculus and the mucosa. Good hemostasis is desirable. (10 figures.)

TUMORS

Godtfredsen, Erik. Eye and nerve symptoms in connection with cranial chordomas. *Acta Ophth.*, 1943, v. 21, pt. 3, pp. 224-236.

The literature which contains 24 reports of cases is briefly reviewed and a case is reported. The initial symptom in the 57 year-old man was unilateral impairment of hearing, followed three years later by abducens paralysis and trigeminal neuralgia. The patient died three and one-half years after the onset of symptoms, and the autopsy revealed a diffuse destruction of the base of the skull and liver metastases. The diagnosis of these tumors is very difficult, and the first symptom frequently results from involvement of the ocular nerves. A diagnosis is possible only in chordomas that proliferate into the naso-pharynx and are accessible to biopsy. (Illustration.) Ray K. Daily.

Lisa, J. R., and Givner, I. Melanoma of the skin with intraocular and orbital metastases. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 422-424.

Melanoma of the eyes or orbits is usually a primary disease and seldom occurs as a metastasis. The authors report a case of metastasis from a primary tumor of the posterior chest wall. Innumerable masses of tumor were found scattered over the body.

At autopsy widespread metastases were found in all the organs except the testes and the left epididymis. There were very numerous tumors in the brain. In each eye there was retinal detachment due to choroidal metastases. Orbital masses were also present. (5 photomicrographs.)

John C. Long.

Mathewson, W. R. **Meningioma of the tuberculum sellae with bitemporal hemianopia.** Brit. Jour. Ophth., 1946, v. 30, Feb., p. 92-102.

A patient with a prechiasmal meningioma and irregular bitemporal hemianopia is described. At operation a very irregular growth of the tumor was found which was the basis of the irregular perimetric findings. Despite some obvious optic atrophy, the patient made a very satisfactory recovery. (10 field charts).

Morris Kaplan.

Páez Allende, Francisco. **Recklinghausen's disease (neurofibromatosis of bulbar conjunctiva).** La Semana Méd., 1946, v. 53, March 28, pp. 572-579.

The patient was a female twin aged 18 years. There was a large tumor formation of the bulbar conjunctiva, histologic analysis of which showed neurofibroma. The patient showed also bodily asymmetry, cutaneous tumors, partial alopecia of the hairy scalp on the side of the affected eye, skeletal lesions, intracranial involvement, and epilepsy. It was planned to extirpate the conjunctival tumor, with insertion of buccal mucosa to fill the breach thus left in the conjunctiva. (7 figures, bibliography.)

W. H. Crisp.

Skydsgaard, Hénning. **Benign rhinopharyngeal tumor (meningioma) with eye symptoms of intracranial origin.**

Acta Ophth., 1944, v. 21, pt. 4, pp. 287-294.

A man, 57 years of age, developed amaurosis with papillary atrophy in the right eye, and a loss of light reaction in the left eye, within a period of ten weeks. A diagnosis of retrobulbar neuritis was made. Ten months later total ophthalmoplegia set in in the right eye, and the visual acuity of the left eye became impaired. Three months later a temporal quadrant hemianopsia for red was found in the left eye, and the ophthalmoplegia cleared up. At this time X-ray studies of the skull were suggestive of sclerosis of the internal carotid. Nasal obstruction led to a rhinological examination 17 months after the onset of the visual difficulties and a naso-pharyngeal tumor as large as a plum was found and removed. The microscopic diagnosis was meningioma. Nine months after removal of the tumor the ocular condition was unchanged.

INJURIES

Dwek, Joseph. **Ecchymotic mask.** J. Internat. Coll. Surgeons, 1946, vol. 9, March-April, pp. 257-265.

Ecchymotic mask is a syndrome that develops after traumatic compression of the chest and abdomen, and is characterized by a cyanotic discoloration of the skin of the face, neck, upper part of the chest, and of the conjunctiva. The lids are edematous. A triangular subconjunctival hemorrhage with the base toward the caruncle and its apex toward the pupil is visible in the palpebral opening. Exophthalmus is present and results from intraorbital hematoma. Mydriasis may be found with a loss of pupillary reaction to

light. Compression of the optic nerve may lead to loss of light perception. Retinal hemorrhages usually lead to atrophy of the disc. Vitreous hemorrhages have been reported.

Porcher, P. and Gilles, E. A method of localizing opaque intraocular foreign bodies. *Ann. d'Ocul.*, 1945, v. 178, Aug., pp. 345-357.

Six roentgenograms are taken of the eye in the following positions; forward, right, left, up, down, and two oblique. For these exposures two films, 6 by 15 inches, are used. The apparatus consists essentially of a localizing tube which contains a plexiglass aluminum-coated mirror observation tube. Attached to it is a metal plate with a thumb screw for raising or lowering a lead ring 24 mm. in diameter, which is contained in a plastic holder. A wire with a long and short arm which shows the position of the eye on the plate projects through a hole exactly in the center of the lead circle. The long arm is attached to an elastic cord which corresponds with the patient's line of fixation. The patient's head is firmly fixed in a holder and the apparatus contains a plate which rests against the nasal wall of the orbit. The basic principle

involved is a triangulation of the lead circle, the wire meridian line of fixation and the intraocular foreign body. The author claims that the results obtained with this method compare favorably with the more complicated Sweet and other methods. Chas. A. Bahn.

Prado, Durval. Strange ocular complication caused from intoxication by sulfadiazine. *Arquivos Brasileiros de Oft.*, 1945, v. 8, Dec., pp. 169-172. (See Section 5, Conjunctiva.)

Saint-Martin, R. A new case of bi-temporal traumatic hemianopsia. *Ophthalmologica*, 1943, v. 105, June, pp. 290-298.

The author describes a case of bi-temporal traumatic hemianopsia with considerable contraction of the nasal portion of the fields which occurred after a fracture of the left frontal bone. The patient, who was examined 11 months after the accident, had a distinct atrophy of the optic nerve and pallor of the nasal segment of the disk of the right eye. There also existed a complete anosmia and an anesthesia of the skin in the region of the right external nasal nerve. The X-ray picture showed a lesion of the left frontal bone at the level of the left minor ring of the sphenoid.

Posttraumatic bitemporal hemianopsias are rare therefore the author briefly reviews the literature and discusses the theories and experiments concerning the mechanism of these injuries. (References.)

Alice R. Deutsch.

Stewart, F. J., Plastic artificial eyes. *Proc. Roy. Soc. Med.*, 1946, v. 39, March, p. 251.

The author feels that mass-produced

plastic ocular prostheses are adequate in the average socket. Despite the occasional idiosyncrasy to methyl methacrylate (one in 10,000), and the ease with which these eyes are scratched, they are distinctly better than glass eyes. Experiments are in progress on hardening the plastic surface.

Benjamin Milder.

Thüer, E. Examination of a bulbus after caterpillar hair injury. *Klin. M. f. Augenh.*, v. 109, May-June, 1943, p. 350.

Injuries from caterpillar hair especially from specimens of the Bombyx and Euproctis families are always a serious and not infrequent occurrence. Thüer reports six cases observed in the Zürich University Eye Hospital. In the most favorable case the patient was admitted to the hospital three days after the injury; the eye recovered in six weeks without recurrences even though all of the hair could not be removed. The lesion was accompanied by the formation of vesicles in the cornea. In all other cases the posterior portions of the globe were involved. The caterpillar hair, which consists of chitin and has minute sharp barbed hooks, wanders into deeper tissues and causes not only mechanical but also toxic damage. The inflammatory process flares up at intervals that varied from 1½ up to 18 years. In no case was removal of all hairs possible. Those embedded in the conjunctiva were removed by means of forceps or excision. Once an iridectomy was performed. In four eyes considerable loss of vision resulted, and two were enucleated. In five of the six cases the injury was a result of youthful frivolity; only one could be regarded as an industrial accident. One

eyeball was examined histologically in serial sections. In 54 nodules 61 fragments of hair were found distributed in the conjunctiva, sclera, iris, ciliary body, vitreous body, choroid, and optic disc. Caseation, as in tuberculosis, was not found in any of the nodules. Giant cells were not frequent and usually had their nuclei peripherally placed. Signs of absorption were noted but rarely. In only three of the 54 nodules were no fragments of hair found. (4 microphotographs, references.)

SYSTEMIC DISEASES AND PARASITES

Bailliant, P. Clinical aspect of ocular tuberculosis. *Ann. d'Ocul.*, 1945, v. 178, Nov., pp. 469-489.

Ocular tuberculosis is an affection of adolescence and more often occurs in boys. Primary infection is rare, its prognosis is often favorable, and it is best treated by means of thermocautery, tuberculin, and radiotherapy. In animals secondary glandular involvement from conjunctival infection may occur without a visible primary conjunctival lesion. Ocular infection secondary to a lacrimal lesion that has extended from the nose is rare. Ocular tuberculomas frequently involve the anterior portion of the uvea; often they are highly inflammatory and vascular, clinically resemble sarcoma, and not infrequently necessitate prompt enucleation. A milder form, nodular iritis, is only slightly inflammatory. Miliary tuberculosis which is due to a bacillema, occurs in the uvea and retina, and varies widely in its severity and duration. This variation depends not only

on the quantity and virulence of the organisms but also on ocular and extraocular allergy. Intraocular infection may extend to the meninges. Phlyctenular keratoconjunctivitis is essentially an allergic reaction which may be accompanied by secondary infection, is usually bilateral, and occurs most frequently in infancy and puberty. Basically, it is an impetigo caused by an antigen that is most frequently tuberculous, and less frequently originates in other organisms, fats or horse serum. The offending antigens are probably secreted in the tears. Tuberculous episcleritis, sclerokeratitis, and interstitial keratitis are also usually allergic reactions, but of longer duration, and recovery is often incomplete. This is especially true of the deep type of scleritis. Among intraocular conditions which pathologically resemble tuberculous lesions are retinal periphlebitis with vitreous hemorrhages, retinal angiomas, Coats' disease, and the syndromes of Heerfordt and Besnier-Bock. Among the diagnostic features noted in tuberculous iridocyclitis are nodules, large gray precipitates, a slow course, folliculosis, lymphocytosis, cicatrization, and incomplete healing. Pigmentation is less marked in tuberculous choroidal lesions than in those caused by syphilis. Pin point granulations in miliary lesions are diagnostically suggestive, as is a dirty gray color. Tuberculosis in antecedents and associates often affords a diagnostic clue. Calcified pulmonary glands, especially those with cloudy margins, may be evidence of slight activity. The uveal tract is especially sensitive to involvement from slight extraocular tuberculous disease. Tuberculous patients usually have vascular hypotension. Unfortunately tu-

berculotoxins have not been identified in the blood.

In hospitals and sanatoria for the tuberculous, ocular tuberculosis is very rare, and its severity is roughly inversely proportionate to the severity of the extraocular lesions. This apparent antagonism of local and general tuberculosis exists in 60 percent of patients with ocular tuberculosis. The stages of tuberculosis are frequently correlated with characteristic ocular manifestations; in the primary or infective stage with phlyctenular disease; in the secondary stage recurrent phlyctenular keratitis, deep keratitis, scleritis, and especially uveal inflammations. In the tertiary stage in which the basic foci of the disease are walled off ocular involvement is rare. Chas. A. Bahn.

Cockburn, C. Ocular cysticercus celulosae. Brit. Jour. Ophth., 1946, v. 30, Feb., pp. 65-74.

The patient was a Jugo-Slav in a British hospital in Italy who complained of defective vision in the right eye. This consisted of a gray haze for about six weeks, then suddenly a well defined object "shaped like a pear leaf" became noticeable. It possessed a stem which had a knob at its end and constantly changed its position "like a serpent's head searching for something." The patient made several drawings of his visual impression that are amazingly accurate pictures of the parasite found. Under atropine mydriasis the entopic image was reduced almost half in size.

Examination revealed a completely spherical, brilliantly colored cyst in the lower portion of the very fluid vitreous to which a miniature tapeworm complete with scolex possessing hooks and suction discs was attached. The head

moved about constantly. Nearby was an area of acute choroiditis through which the cyst had apparently ruptured though no retinal separation was present.

The cyst was delivered with the aid of a scleral hook through a scleral section. There was considerable loss of fluid vitreous. After a stormy convalescence the eye became quiet and perceived light. The parasite was *taenia solium*. No adult infestation was present in this man. The ovum apparently had been swallowed, had penetrated the intestinal wall and entered the portal circulation, the arterial system, and finally the choroid by way of the ophthalmic artery. Morris Kaplan.

Desvignes, P. Aneurysms of the intracranial segment of the internal carotid. *Arch. d'Opht.*, 1945, v. 5, no. 3, p. 303.

This comprehensive review with illustrative case reports is difficult to abstract. The author stresses the fact that ocular symptoms commonly bring this condition to the attention of the ophthalmologist, upon whom rests the burden of early diagnosis, although treatment is necessarily neurosurgical. He also stresses the important role that cerebral arteriography plays in the diagnosis.

Important points discussed include (1) anatomical variations of the carotid, (2) clinical signs of aneurysm including ophthalmoplegia, meningeal hemorrhage, and opticochiasmic compression, all illustrated by case reports, (3) evolution, and (4) therapy. The author discusses in detail the various eye signs and mentions that a progressive exophthalmos which can be pulsating in type may occur in certain cases. Radiography generally shows

erosions of the anterior clinoid processes and abnormal vascular shadows with or without arterial calcification.

Focal symptoms depend upon the anatomical localization of the aneurysm. If it is in the cavernous sinus, unilateral loss in visual acuity, diplopia, unilateral headaches, facial neuralgias, corneal anaesthesia, and sometimes slight exophthalmos may result. If the aneurysm ruptures, the characteristic picture of arterio-venous aneurysm with pulsating exophthalmos may result. If the aneurysm is localized at the termination of the internal carotid, or on one of its terminal branches, there may be violent retro-orbital headaches, sometimes with vomiting and loss of consciousness. Sudden death is the usual end result. If the aneurysm produces a compression of the chiasm, unilateral loss in visual acuity is the common symptom but bitemporal hemianopsia may supervene. If the lesion is left untreated blindness results.

Possibilities of medical treatment are discussed, including injection of sclerosing solutions, but surgical therapy offers more hope. Pulsating exophthalmos in particular has been successfully treated by carotid ligation and the author considers this procedure as life saving in the prevention of aneurysmal rupture. Internal carotid ligature is useless, however, when the terminal branches of the artery are involved, and direct surgical intervention may be necessary. Phillips Thygeson.

Falls, H. F., and Beall, J. G. Ocular varicella. *Arch. of Ophth.*, 1945, v. 34, Nov.-Dec., pp. 411-412. (See Section 6, Cornea and sclera.)

Gördüren, Süreyya. A case of acro-

cephaly. Göz Klinigi, 1946, v. 3, no. 4, pp. 53-62.

The writer describes a young patient who had been suffering from acrocephaly, nystagmus, exophthalmos, divergent strabismus, and a primary atrophy of the optic nerve.

A projection on the occipital region of the skull, as large as a goose's egg, accompanied the acrocephalic change. It is assumed that the closure of the lambdoidal suture was retarded in consequence of which the skull, having no resistance against the intracranial pressure, became malformed.

An accompanying anosmia may have been caused by pressure on the olfactory nerve or as a result of a specific meningitis or a pachymeningitis. The Wassermann reaction of the blood was three plus. I. E. Gaynon.

Kayser, B. Distant effect on both eyes originating from a focus in the mandible with unilateral hemianopsia. (Self-observation.) Klin. M. f. Augenh., 1943, v. 109, May-June, p. 413.

Kayser noticed a horizontal unilateral hemianopsia developing slowly and insiduously in his hitherto normal and not irritated left eye. The scotoma was absolute and objective but did not interfere much with vision since the macula was not affected, but a pulsation synchronous with the heart beat was present in the eye. Two weeks later there was sudden malaise, great fatigue, and severe bilateral disturbance of the function of the eyes. Reading, writing, and fusion became impossible. The supraorbital rim and region of the frontal sinus were tender to touch. He had vertigo and light-headedness and his gait became spastic. Internal and rhinological examinations were negative. Bed rest gave no

noticeable relief. Two months later a sore tooth in the lower jaw was treated for granuloma. The symptoms disappeared rapidly. F. Nelson.

Öztürk, M. H. A case of Behçet's disease. Ophthalmologica, 1944, v. 108, Dec., pp. 288-292.

Behçet's disease is a complex of symptoms characterized by aphthous ulcers in the mouth, ulcerations on the genitals, erythematous nodules on the legs (erythema nodosum), and by keratitis, iritis, and hypopyon in the eye. These changes do not always occur concurrently, but may be separated by months or even years. Behçet who described the disease a few years ago assumed that a virus is the causal agent. The author describes a patient, observed in Istanbul, who gave a history of attacks of fever and ulcerations in the mouth and on the genitals. The eye symptoms occurred later with edema and opacification of the cornea, hypopyon, later hyphema, and secondary glaucoma. Only one eye was involved and the symptoms varied in intensity from time to time. Phlebitis and erythema of the legs were also present. Treatment with sulfonamides and vitamins B and C was unsatisfactory. Max Hirschfelder.

Heise, F. H. Treatment of experimental ocular tuberculosis with promin. *Am. Rev. Tuberc.*, 1946, v. 53, Feb., p. 175.

In order to evaluate the therapeutic effect of promin (a derivative of diamino-diphenyl-sulfone) on tuberculosis, the authors employed direct clinical observation of tuberculous lesions of the eye. Suspensions of tubercle bacilli were injected into the anterior chamber of the eyes of guinea pig. The resulting infection was graded into five groups according to severity of the findings.

One group of vaccinated guinea pigs in whom tuberculous ocular infection had been produced was treated with promin administered orally, while another group received the drug orally and locally (by instillation into the conjunctival sac). In both these groups, there was an initial allergic response, followed by improvement for one week, then a gradual increase in severity to grade 3 infection. Similarly infected vaccinated guinea pigs, that did not receive promin, were found to have more severe ocular infection (grade 4). Control animals that had not been vaccinated beforehand with tubercle bacilli, and had not received promin, developed a grade 5 reaction (corneal necrosis and perforation), and died.

The experiment demonstrated that promin was of value early in the course of tuberculosis, as evidenced by the clinical observations and corroborated by the autopsy findings at the conclusion of the 295-day experiment. No cures were effected but there was a definite retardation of the tuberculous lesions. Benjamin Milder.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Barnett Albert. Plato's conceptions of light and sight. *The Optician*, 1946, v. 111, May 10, pp. 289-292.

The article consists of quotations from the "Republic." Plato gives many examples of what we today would call the phenomena of light and dark adaptation, and states "that the bewilderments of the eyes are of two kinds, and arise from two causes either coming out of light, or from going into the light." In Book X, Plato discusses the refracting property of water because of which an object that appears straight when looked at out of the water seems broken when in the water. In the discussion of visual beams, sight is an internal fire that flows from the eyes in a smooth and dense stream and passes through the pure element. When this combines with external light, the stream of vision reaches the soul and causes that perception called sight. He also discusses reflection and the formation of images in mirrors.

Colors are a flame which emanates from any part of the body and has particles corresponding to the sense of sight. Particles having the same size as sight are transparent. White dilates the visual ray and black contracts it. The formation of colors is discussed as caused by the various fires, the proportions of which give the various hues. There is an intermediate hue of red. Red and white make auburn. Red, white, and black make purple.

Fortner, E. N. A Public School program for the visually handicapped in Oregon. *Sight-Saving Review*, 1945, v. 15, Winter, pp. 212-220.

School teachers are trained to test vision by means of the Snellen chart. All children whose visual acuity is 20/40 or less, or who have asthenopia or strabismus, are referred to their family doctor or to a clinic. The Division of Special Education provides textbooks with clear type where needed. During the past two years 2700 children have been examined in the educational clinics, and 150 of them have needed books with large type. I. E. Gaynon.

Hilliard, R. Public assistance for the blind in Illinois. *Illinois M. J.*, 1945, v. 88, Oct., p. 199.

The Illinois Public Aid Commission has had the responsibility for the administration of the Blind Assistance Act since its passage in June of 1943. This act provides assistance to needy blind persons and its provisions are

such that Social Security funds are made available to meet 50 percent of the cost up to a maximum of \$40.00 per month.

A committee was appointed to advise on the social and medical aspects of the program.

The definition of blindness formulated by the Sub-committee on Ophthalmology reads as follows: "In terms of ophthalmic measurement, central visual acuity of 20/200 or less in the better eye, with correcting glasses, is generally considered economic blindness. A field loss in which the visual field efficiency is reduced to 30 percent or less may be considered equally disabling, as may certain ocular conditions which do not necessarily involve visual acuity or peripheral field loss, but which constitute severe visual handicaps."

The applicant must furnish evidence of financial need, verification of age, and proof of blindness. The applicant must have reached the age of 18 years and must be examined by an ophthalmologist.

The examiner reports his findings on a form which the Commission supplies and mails it to the Supervising Ophthalmologist who reviews and evaluates the findings in terms of the definition before he certifies that the applicant is blind.

The assistance is not always financial. The applicant may be given medical care or help in social and economic rehabilitation.

The Commission has worked out cooperative agreements with the Division of Visitation of the Adult Blind; Division of Vocational Rehabilitation; Illinois Eye and Ear Infirmary; Cook County Hospital; the sheltered workshop of the Department of Public Wel-

fare; Trachoma Clinics; and many private social and welfare agencies.

Theodore M. Shapira.

Jones, Tom. *Via optica*. Quart. Bull. Northwestern Univ. Med. School, 1946, v. 20, Spring, pp. 71-76.

The writer has been concerned for years with the production of visual teaching media and thinks one should exploit this method of communication of knowledge and information. We are still clinging to the traditional lecture hall methods; experience has shown that these methods are insufficient and time consuming as compared to the newer visual and audio-visual technique which can be integrated towards a fuller and more lasting understanding. Models, charts, photographs, drawings and all worthy graphic material should be kept displayed in classrooms, halls, or wherever suitable space permits. The growth of visual education has imposed upon the planners of our medical schools the need for providing space for the function of the graphic media of medical education and for providing facilities for the expression of the language of vision. Students' capacity of absorption varies. Some require more time than others to comprehend and coördinate the material of their course. A variety of well selected visual aids placed where they can be seen becomes an environmental factor which silently and unobtrusively contributes to their wider understanding. Students like to visit these interesting places where they can solidify and expand their class-room studies; they are grateful for the opportunity to observe and contemplate at leisure material that will supplement and illuminate what they learn in the class-room and laboratory. Two figures ac-

company the essay which illustrate some aspects of visual instruction.

Ray K. Daily

Lee, O. S. *Chinese native ophthalmology*. J. Iowa M. Soc., 1946, v. 36, March, pp. 91-98.

This paper covering the history and conceptions of Chinese ophthalmology is not suitable for condensation. Some of the more striking data follow. Needling was supposedly originated in 2679 B.C., and the first work on this subject was published in 250 B.C. Through the influence of Buddhism, Indian medicine was introduced into China. The three main texts of the era included a description of conjunctivitis, cataract, night blindness, glaucoma, trichiasis and operation for cataract.

The Chinese concept of the functions of the organs of the body and their ideas on the principles and practice of medicine are based on the theory of cosmogony, which is active today. There is no literature dealing with the anatomy of the eye. Ocular disease is always associated with disease of the viscera and internal organs. Diseases of the eye are divided into diseases of the internal eye, of the external eye, and of the corneal membrane. The causes and treatment of pterygium,

hypermetropia, trachoma, redevye, glaucoma, pannus, iris prolapse, interstitial keratitis, trichiasis, blepharitis are illuminated from the Chinese point of view. The surgery for pterygium and cataract, and optical glass came into use between 1766-140 B.C. The notation for the refractive power of lenses was not in diopters, but according to the Chinese zodiac. Plus lenses were used only for presbyopia. They were not prescribed for the young even if needed, for the young did not dare to use the same lenses as their elders.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.

904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. James Cornelius Braswell, Tulsa, Oklahoma, died May 31, 1946, aged 53 years.

Dr. Grady Edward Clay, Atlanta, Georgia, died July 11, 1946, aged 56 years.

Dr. Robert Lewis Crockett, Oneida, New York, died May 27, 1946, aged 70 years.

Dr. Edward Keith Ellis, Boston, Massachusetts, died June 7, 1946, aged 66 years.

Dr. Frederick James O'Conner, Fayetteville, New York, died March 29, 1946, aged 62 years.

MISCELLANEOUS

The National Society for the Prevention of Blindness announces a three-day conference, November 25, 26, and 27, 1946, at the Hotel Pennsylvania, New York.

During September and October, a series of meetings are being held in the Department of Ophthalmology, University of Glasgow. The general arrangements are similar to those for the series held a year ago. The program includes: On September 11th a paper on "Irregular dominance in hereditary nystagmus," by Prof. W. J. B. Riddell; on September 18th, a paper entitled "Etiology and treatment of paralytic squint," by Dr. W. O. G. Taylor.

Dr. J. B. Gaylor will speak on September 25th. His paper is on "Electroencephalography in retinal disease." On October 2d, Mr. John Foster will present a paper entitled "An ophthalmic tour of Switzerland." Dr. Michaelson will discuss "Proptosis and exophthalmos" on October 9th, and on October 16th, Professor Loewenstein will give a paper on "Phakomatosis."

The meetings are open to all medical practitioners and senior students interested in ophthalmology. Tea is served after the paper has been read, and a discussion follows.

A unit has been established to administer the new New York State ophthalmic law requiring, for the first time, the licensing of persons engaged in dispensing eyeglasses, spectacles, and lenses, according to the department of education in the New York Times, July 15th. The new unit is in the department's bureau of qualifying certificates and professional examinations. The commissioner of education has appointed an advisory board to assist in administering the law, consisting of: Dr. Walter

Hipp, ophthalmologist, 140 East Fifty-Fourth Street, New York; Harlow Fuller, optometrist, Syracuse; Henry B. Carpenter, optician, Guild of Prescription Opticians of America, Inc., Syracuse; Edward J. Boyes, optician, 659 Lexington Avenue, New York; Walter A. Blocker, optician, 604 Madison Avenue, New York.

Persons engaged in ophthalmic dispensing must be licensed by July 1, 1947. Those who have been engaged in ophthalmic dispensing for three years before enactment of the law, April 10, 1946, may qualify for licenses by submitting evidence that they were thus principally engaged in the state for at least that period and evidence of good moral character. The period of filing is extended beyond July 1, 1947, for war veterans who were ophthalmic dispensers for not less than three years before they entered the armed forces. After July 1, 1947, a candidate for the required examination must present evidence of an approved secondary school course and the completion of either a one-year course of study in a school of ophthalmic dispensing registered by the state education department or one year of training or experience in ophthalmic dispensing under the supervision of an ophthalmic dispenser, physician, or optometrist. Thus far no schools of ophthalmic dispensing have been registered with the department, it is reported.

SOCIETIES

At a recent meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology, Dr. Thomas F. Furlong, Jr., Ardmore, was elected president. Among other officers are: Dr. Benjamin F. Souders, Reading, secretary, and Dr. William E. Grove, Johnstown, treasurer. The 1947 meeting of the society will be at the Hotel Hershey, Hershey, in April.

PERSONALS

Dr. Bertha A. Klien has been appointed associate professor of ophthalmology at Northwestern University Medical School. She has been serving as associate professor of ophthalmology at the University of Illinois College of Medicine.

Dr. James N. Greear, Jr., 1740 M. Street, N.W., Washington, D.C., has been named as consultant in ophthalmology to the Secretary of War.

A STUDY OF LEWISITE LESIONS OF THE EYES OF RABBITS

IDA MANN, A. PIRIE, AND B. D. PULLINGER

London and Oxford, England

The effects of mustard gas when applied to the rabbit's eye by various methods have been set out in a previous publication.¹ We consider it of interest to describe a parallel series of experiments using Lewisite (β -chlorovinyl-dichlorarsine), since the actions of the two chemical-warfare agents appear to differ in all important points. This is only to be expected, for mustard and Lewisite react largely with different groups in the protein molecule, and the difference in the pathologic changes in the eye lesions probably reflects this fundamental difference.

The characteristics of mustard-gas lesions may be briefly summarized as follows:

1. Application is not painful, and symptoms do not appear for some hours.
2. The pupillary reaction is not affected.
3. Perforation and loss of an eye are caused only by relatively large doses (0.005 c.c.), and even then are long delayed. Perforation never occurs as a primary lesion before the stage of vascularization.
4. Vascularization never occurs unless the limbus is damaged by the mustard (that is, purely corneal lesions do not vascularize).
5. Vascular lesions do not all perforate; they tend to be chronic, to relapse, and to show intracorneal

hemorrhages from newly formed vessels, which latter are of peculiar and characteristic form.

6. Cholesterin and other lipid scars follow some vascular lesions, and subsequently these tend to break down² (delayed mustard-gas keratitis).
7. Edema of conjunctiva and cornea is present, but not excessive.
8. Iris and ciliary body are relatively little involved. There is no late effect on pigment.
9. Characteristic vessels form in cornea and conjunctiva.

In the case of Lewisite we shall show that:

1. The action is immediate and painful.
2. There is an immediate strong miotic action.
3. Perforation and loss of an eye are caused with relatively small doses (0.001 c.c.); perforation may occur within a few days without vascularization, or later after the entry of blood vessels.
4. Vascularization is independent of the site of the primary lesion; it occurs when a sufficient dose of the Lewisite reaches either the cornea or the limbus.
5. All lesions run a definite course to recovery or destruction; not all vascular lesions perforate; there are no relapses and no recurrent hemorrhages.

EXPERIMENTAL PROCEDURE

- Animals used.* A variety of rabbits was used, including black, with dark-brown eyes; crossed Dutch, with blue eyes; some with gray, and some with heterochromic eyes. The animals with blue eyes were used to study the effect on iris vessels, since dilatation of vessels and small hemorrhages can be most easily seen in them; those with brown eyes were used to study depigmentation of the mesodermal pigment of the iris; and those with either blue or brown eyes could be used in the observation of proliferating limbal conjunctival pigment rings in most individuals. Albino eyes are not suitable, as they are very difficult to observe accurately during life; moreover, many of the reactions seen in pigmented rabbits do not occur in the albino. Twenty-seven experiments were performed.

Method of application of Lewisite.

Three different methods of application were used.

1. The rabbits were anesthetized, and the lids held open. The center of the cornea was exposed to Lewisite vapor obtained from cotton-wool pledgets soaked with Lewisite inserted into the open ends of glass tubes of varying sizes. The tubes were then held over, but not in contact with, the part of the eye required, for varying lengths of time. The dosage was impossible to standardize, but a series of "very mild" and "mild" lesions was produced.

2. The rabbits were anesthetized, and small glass applicators, similar to those described in our mustard experiments, were used. They delivered between 0.1 mg. and 0.2 mg. of liquid Lewisite, as determined by arsenic estimations. The lids were held open, and applications made to the cornea or the limbus, as re-

6. Cholesterin and other lipid scars do not occur, and there is no late breakdown due to them. The end result of a nonperforating severe lesion is dense fibrous scarring with pigment proliferation on the corneal and conjunctival epithelium.

7. Edema of the lids and conjunctiva is immediate and severe; edema of the cornea is extreme with all but the smallest doses.

8. Involvement of the iris and ciliary body is early and severe, followed by gradual depigmentation and shrinkage of the iris stroma.

9. The corneal vessels do not show the characteristic varicosities of mustard vessels. They are straight and evenly and radially arranged. No characteristic vessels appear in the conjunctiva.

These conclusions show that Lewisite has a much more destructive and extensive effect than mustard gas. It is much more difficult, therefore, to produce minimal lesions and, indeed, this can be done only by means of short exposures to vapor, whereas in the case of mustard gas, minimal lesions can be obtained with liquid.

The clinical report which follows is based on observations of lesions of varying severity obtained by treating 27 rabbit eyes with varying amounts of Lewisite vapor or liquid. The lesions are classified according to severity. "Very mild" and "mild" lesions are those which (after short exposures to vapor) recovered without passing through a stage of corneal vascularization. "Severe" lesions (produced by longer exposure to vapor) recovered with slight permanent scarring after partial vascularization. In "very severe" lesions, the eye was lost by shrinking and corneal scarring with or without perforation.

quired. "Severe" lesions were produced in this way.

3. Unanesthetized rabbits were used with the same applicators as in method 2, but the rabbits were allowed to blink so that the liquid was immediately spread out and involved cornea, conjunctiva, and lids. This type of lesion simulates that likely to occur in persons exposed to Lewisite spray.

EXPERIMENTAL RESULTS

GROUP I.

Very mild lesions. Ten eyes were examined. All the injuries in this group were produced by vapor, and the rabbits were anesthetized, so that it is not known whether exposure to Lewisite vapor is painful in rabbits.*

At the time of application the eyes were observed for 15 minutes, and at frequent intervals after that. During the first 15 minutes, there was no conspicuous change in the corneal epithelium, except that it showed slight pitting due to exposure, and occasionally appeared faintly grayish. In 15 minutes, isolated hydropic cells began to appear in the epithelium. These increased to a definite bedewing in $1\frac{1}{2}$ hours. The pupil did not contract, but the iris vessels flushed in most eyes within 5 minutes; in one rabbit in $3\frac{1}{2}$ minutes. Lacrimation was variable, but usually appeared in from 6 to 10 minutes.

* Judging from the sensations of two human beings exposed to extremely small concentrations of Lewisite and of ethyl dichlorarsine, respectively, a stinging sensation is felt immediately, and it would be almost impossible to keep the eyes open for anything like the time needed to produce a serious corneal lesion. In respect of sensory irritation, Lewisite vapor differs conspicuously from mustard gas, and the risk to the eyes from vapor might, therefore, be small, in spite of its much more violent action. The main risk would be from the the entry of a single droplet, such as was used in the third set of experiments.

In $1\frac{1}{2}$ hours, or less, the exposed area revealed a fine punctate staining with fluorescein. This increased in density for approximately 7 hours and then became less. It had practically disappeared at the end of 24 hours and, in all eyes, cleared up completely within 36 hours.

Slight mucopurulent discharge appeared, derived especially from the third lid, which became somewhat edematous in $2\frac{1}{4}$ hours. This edema and discharge cleared up in all eyes within 36 hours.

Interesting changes occurred in the substantia propria and the endothelium in these very mild injuries. They were observed in detail with the slitlamp. Within an hour, the corneal corpuscles could be recognized in direct illumination much more easily and over a wider area than normal. They appeared to be swelling, but were not opaque (that is, not visible by retroillumination or sclerotic scatter). The endothelium, however, in about half the eyes showed a widespread and peculiar change, the cells swelling up and producing a series of faint linear ridges arranged in a diamond pattern, easily visible by retroillumination (fig. 1). It was possible to watch the development of this diamond pattern, which formed quite rapidly at the end of the first hour, taking about 10 minutes to become complete.

During the same time, irregularities of the epi- and endothelial surfaces were seen forming in the zones of specular reflection. These appearances were transitory, lasting from 2 to 3 hours to a day, not seen in every case, and gradually being replaced by a condition of uniform swelling of every endothelial cell. This swelling was much greater than ordinary "endothelial bedewing" and was easily visible all over the cornea (fig. 2). When it subsided, large Hassle-Henle bodies sometimes appeared. It began to subside

Figs. 1 and 2 (Mann *et al.*). Fig. 1, Diamond pattern on the endothelium seen by retroillumination. Fig. 2a, Edema of endothelial cells—very gross bedewing. 2b, Hassle-Henle bodies formed after healing.

in 3 days and had gone in 5 days, or less. The swelling of the corneal corpuscles sometimes continued. They became increasingly easily visible, being seen not only by direct illumination, but soon (24 hours) by retroillumination as well, and in two days presenting a characteristic appearance. They were then very swollen, fluffy, and opaque, and could be seen by light scattered within the cornea (corneal or sclerotic scatter), as well as by retroillumination. A profound change had occurred in them which completely altered their physical properties, including their index of refraction. They will be referred to as "opaque corneal corpuscles." They appeared through the whole thickness of the cornea (fig. 3).

At the same time, the surface layers of the substantia propria became split apart and edematous, but in these very mild lesions the stratification did not extend deeper than the superficial quarter and might not even occur. It reached its maximum in 3 to 4 days and then subsided rapidly, within the next 24 hours, disappearing by the 5th day.

The changes in the iris might not progress beyond the initial hyperemia, which subsided in 24 hours. In some eyes, however, although no aqueous flare was observed, a small amount of deposit, possibly fibrinous, was seen on the endothelium on the fourth day. In no case was

Fig. 3a (Mann *et al.*). Opaque corneal corpuscles seen by sclerotic scatter and in the narrow beam of the slitlamp. In a central Lewisite vapor lesion. Those in the center of the lesion are completely destroyed, those at the periphery are all opaque. Farther out they are more scattered.

Fig. 3b (Mann *et al.*). In a minimal lesion, showing as in fig. 3a, destruction of the central cells and opacity of those around the periphery. Fig. 3c, The lesion in b in the narrow beam. any alteration in the color of the iris seen in either blue- or brown-eyed rabbits, nor was there any disturbance of uveal pigment or of the lens capsule.

The fate of the "opaque corneal corpuscles" requires histologic investigation for its complete elucidation, but with a slitlamp certain changes were observed. It was possible by directing the vapor towards the center of the cornea to produce a localized circular lesion. The circumference of the circle on the first day showed large numbers of these opaque cells (fig. 3). Within this ring, there was a narrow clear zone. In the center of the circle, the superficial layers of the substantia propria were edematous, and the deeper layers contained remnants and debris of cells, with perhaps a few opaque cells in the deepest layers only. The opaque condition of the cells appeared to be an intermediate one between normality and complete destruction. This appearance continued for 3 or 4 days and then, in the zone of opaque cells, very fine short processes were made out in connection with some of the cells. These fine processes increased in size and in number, and the cell bodies became less visible.

From the 5th to the 8th day, the ring was slowly transformed from a ring of opaque cells to a circular zone of long silky fibrils (fig. 4). These were seen progressing towards the center of the circle, which then looked clear and almost normal, though it contained some opaque cells. By about the 12th day, the whole lesion was transformed into a patch of fine silkiness. This appearance slowly faded, and no trace of the lesion was finally left. In one case the cornea was completely normal in 9 days; in others, faint silkiness could still be detected in a month. In most, no trace of any abnormality could be found in 6 weeks.

This type of lesion is, therefore, characterized by very transient conjunc-

tival and iris irritations and by damage to corneal corpuscles. Some kind of repair is effected, possibly originating in the partially damaged corneal corpuscles.

GROUP II.

Mild vapor lesion. Two eyes were examined in this group. They were not very different from the lesions in Group I, except that they were more severe and longer in clearing up. Their characteristic

Fig. 4 (Mann *et al.*). Changes in the opaque corneal corpuscles: a, At the 5th day they are seen to be elongating. b, At the 8th day they are transformed into a ring of silky fibrils.

was a short period of intense edema of the cornea, with increased activity of the limbal blood vessels, which appeared about to enter the cornea and then retrogressed. The contraction of the pupil, which will be seen to be characteristic of the next group, occurred in the worse of these two mild lesions.

The course of events in this eye is typical. A grayish patch was seen almost immediately on the epithelium. The pupil contracted, and the iris began to flush within half an hour. The typical diamond pattern appeared on the endothelium in an hour, when the smallest iris capillaries were also dilating. In 2 hours and 20 minutes, the eyelids looked pink, and the third lid showed slight edema. The edema of the substantia propria was beginning. Slight discharge appeared later, and at 5 hours and 40 minutes, the epithelium over the point of maximum exposure had sloughed off, and the edema of the substantia

propria had considerably increased. At the end of 24 hours, the cornea looked "steamy" and was too hazy for any details of iris or anterior chamber to be seen. In 2 days the cornea was intensely swollen, an aqueous flare could be seen, and the eye looked worse, though there was no more discharge. The cornea was very much increased in thickness, was waterlogged, and appeared to be split into two layers: a superficial layer—very edematous and pale blue in color, with wide separation of the fibrils—and a deeper, more dense and homogenous layer, of a more yellow color (fig. 5). The appearance was peculiar and characteristic, the eye seeming to bulge, the contour of the cornea being almost conical, and the eyes looking rather like moonstones and definitely bluish in color. The term "moonstone eye" was coined to describe the condition. This continued for 5 days, when the limbal blood vessels became active and a few superficial loops crossed the limbus on to the cornea. The iritis had, however, subsided completely, leaving two small posterior synechiae and a fibrinous deposit on the endothelium.

In 6 days, the vessels disappeared, the edema started to subside, and the eye to improve rapidly, so that in 15 days it appeared perfectly normal to macroscopic examination. The slitlamp, however, showed a fine silkiness which persisted in its densest part for $5\frac{1}{2}$ months and may be permanent. It is, however, too slight to interfere with vision, and the eye may be considered normal.

This rabbit showed in a minor degree the edema which is so characteristic of the more severe lesions.

GROUP III.

Severe vapor lesion. Three eyes were examined in this group which showed partial recovery with fair function, after vascularization. At the time of application,

the corneal epithelium became grayish, and the pupil contracted strongly. The early changes were similar to those in Group II; namely, changes in the epithelium and endothelium, and flushing of the iris. The diamond pattern appeared on the endothelium in half an hour, and edema of the superficial layers of the substantia propria was also beginning at that time. An aqueous flare was noted at 2 hours. All the changes began slightly earlier and were more evident than in Group II. The substantia propria began to split into layers at 4 hours, and the edema was advanced in 24 hours, so that the cornea had a distinct opalescent appearance and was almost at the moonstone stage.

At 24 hours, there was a staining area in the center of the cornea, corresponding to the region of epithelial destruction. The remaining epithelium and endothelium were heavily bedewed. The injected iris showed through the edematous cornea with a distinct universal red glow. There was an aqueous flare, and free cells were seen in the aqueous. A curious pattern of concentric circles of fine pigmented dots could be seen on the anterior surface of the lens capsule, probably a deposit from the aqueous of blood and pigment-containing cells. There was little or no discharge, although the conjunctiva was hyperemic.

In 2 days the corneas presented the typical moonstone appearance. They were swollen and bulging, bedewed and edematous, and no details of cells could be seen. The staining had practically gone. The iris still appeared bright red.

The moonstone appearance increased for 5 days and did not then subside, as it did in Group II. Instead, on the 5th or 6th day, the engorged limbal blood vessels began to invade the cornea around almost the whole circumference simultaneously. These vessels were both super-

around towards the center. As they advanced, they became very regularly arranged in a radial row of thin parallel channels of even caliber, lying in the superficial layers of the substantia

ficial and deep. The deeper ones were larger and sent out more branches than the superficial ones; but all of them were straighter, of more even caliber, and more regular arrangement than those seen in a

Fig. 6

Fig. 12

Fig. 6 (Mann *et al.*). Vascularization: a, deep vessels; b, superficial vessels preceded by capillary hemorrhages; c, radially arranged superficial vessels. A deep vessel is seen near the top.
Fig. 12 (Mann *et al.*). Two scarred and shrunken eyes showing bizarre pigment proliferation.

mustard-gas vascularization. They were preceded by small intracorneal hemorrhages, which soon cleared up and did not tend to recur over long periods, as did those typical of mustard gas (fig. 6). The vessels advanced for 14 to 18 days, growing steadily in from the limbus all

propria. At their extending tips, they branched and formed a very rich capillary network, with a few detached ends and small hemorrhages only. They resembled the new vessels of granulation tissue much more than do those of mustard-gas vascularization, which do not end in a

capillary arborization, but as straight tips. After 18 days, the edema began to clear rapidly, the vessels ceased to advance, became thinner, and the fine capillaries disappeared rapidly. The larger radial trunks also disappeared, except for a few of the largest ones.

In 3 weeks the edema of the substantia propria disappeared, the cornea returned to its normal thickness, although it still showed disturbance of endothelium (beaten-silver reflex), and there might be slight epithelial bedeviling. The vessels were all narrow and empty, or showed slow and interrupted circulation only. The larger trunks alone were visible. As the edema of the cornea subsided, a fine silky change was seen all over it, similar to that seen in the other groups, although in Group III the excessive edema obscured the preceding stage of opaque corneal corpuscles. This fine silkiness slowly disappeared in about 6 months.

As the cornea cleared (after the 18th day), the iris again became visible. It was then seen that profound changes had occurred in it. Brown-eyed rabbits showed these changes best. At 18 days, or sooner, it was noticed that the iris, to macroscopic observation, no longer looked dark brown, as it was originally, or bright or dull red, as it was at the height of the reaction, but had become light blue. This remarkable change might involve the whole iris, but was most conspicuous in the circum pupillary zone over half the width of the iris or more (fig. 7). The blue patches might be circinate in outline, or confluent; in some eyes, only a narrow peripheral ring of brown was left. If examined in more detail, the pupil was seen to be somewhat dilated, was irregular in outline, and possibly showed a few posterior synechiae. Here and there, usually above and below, there was considerable ectropion of the uvea, as though the dilated appearance of the pupil were

GROUP IV.

Very severe lesions. These lesions ended in loss of the eye. Twelve eyes

due to contraction of the stroma. In some cases this was so excessive at one or two spots that the tips of the ciliary processes were pulled right around, so that they appeared at the edge of the pupil. The sphincter was not destroyed, since these distorted pupils showed a reaction to light. The stroma of the iris had undergone a peculiar change. In the brown zone at the periphery, the chromatophores appeared normal, bright brown, with long interlacing processes, and spread out in an even sheet. As the light-blue areas were approached, the chromatophores became darker in color, lost their processes, and resembled very dark-brown spherical and amorphous deposits, rather than cells. This withdrawal of processes was confirmed microscopically. The cells were thickly aggregated at the edges of the blue areas and were present all over those as isolated dark spots dotted over the unpigmented stroma. This stroma, exposed by the retraction of the chromatophores, appeared at the 18th day somewhat edematous and translucent. The vessel walls were easily seen and appeared normal. The stroma finally looked fluffy and atrophic and, at times, as if the surface layer had been torn off, leaving odd tags and fringes floating loosely attached. This change and the ectropion of the uvea appears to be permanent, having been observed for 8 months without further alteration. No change was observed in the ectodermal uveal pigment, other than ectropion. It was not degenerated.

These eyes appeared to have excellent function in spite of the residue of the severe iritis. The fundi were examined with an ophthalmoscope and appeared normal.

from rabbit to rabbit. In 5½ minutes there was a faint surface haze over the whole cornea. In 10 minutes, the conjunctival vessels were flushed. In 15 minutes, a severe chemosis of the ocular and

Fig. 8 (Mann *et al.*). Severe chemosis of ocular or palpebral conjunctiva 30 minutes after a droplet of liquid Lewisite entered the eye.

palpebral conjunctiva was beginning, even in eyes in which the cornea alone had been treated. In those in which the conjunctiva was injured, it appeared sooner, but was otherwise similar. The areas involved stained only very faintly with fluorescein at this stage (fig. 8).

In half an hour the corneal epithelium had become so edematous that it was impossible to see any details of the iris. In 1½ hours, the epithelium was beginning to loosen and slough off, giving an almost universal stain with fluorescein. In 4 hours, or less, there was a watery discharge containing cells, and the chemosis had reached surprising proportions. The entire conjunctiva, ocular and palpebral, was enormously swollen, so that the lids were held right away from the eye, sometimes bulging more than half an inch. The cornea was overlapped by folds of gelatinous injected conjunctiva, the appearance of the eye being striking and peculiar. The swollen conjunctiva was covered with fine vessels, and small petechiae were seen to develop. The lymphatics were widely open and were easily observable

were examined. The initial sequence of events was similar, but more rapid and more severe than that seen in Group III. Some of the lesions in this group of 12 eyes were produced by a single droplet of liquid Lewisite; others were caused by exposure to vapor for varying times, up to 20 minutes. In some eyes the cornea alone was injured, in others the limbus, and in others again the cornea, limbus, lids, and conjunctiva were affected. Thus, some of the original injuries were more severe than others, although all the eyes were finally lost. The exact method of application did not appear to be important, except in those cases where the lids and conjunctiva were extensively injured, when the eye was lost in about half the usual time, and many of the stages of destruction were telescoped.

As a point of interest, it may be mentioned here that liquid Lewisite applied to the ocular conjunctiva increases the transparency of the sclera so that the uveal pigment shows through in 2 minutes as a black spot. This disappears within a day.

The eyes can be divided roughly into (a) those lost after initial vascularization and (b) those which perforated before vessels had entered the cornea. (a) The course of events in an eye lost after initial vascularization was as follows: The site of application of the liquid or vapor became immediately opaque. When liquid was used the droplet showed no tendency to slide. It appeared to soak into the cornea almost instantaneously, the opaque area increasing in size by spreading concentrically for about two minutes. The Lewisite then reached the aqueous, where it diffused rapidly, the whole iris flushing, and the pupil contracting very quickly and strongly, so that in 2½ minutes, it was pinpoint in size. There was some secretion of clear tears but this was variable

as clear, distended, optically-empty tubes in the narrow beam of the slitlamp (fig. 9). The corneal epithelium had nearly all sloughed off. There was edema of the substantia propria in its superficial fourth. Descemet's membrane looked corrugated, and the pupil was still contracted. In seven hours the petechiae had increased in number and size. The whole cornea stained. The edema involved nearly its whole thickness. No details of cells or of the anterior chamber were seen.

In 24 hours a remarkable improvement in the chemosis had occurred, but the eye was much worse. The lids were again in apposition to the globe. There was very little discharge. Large conjunctival hemorrhages had appeared. The whole cornea stained, and the stain reached the aqueous in 5 minutes.

The anterior chamber was now visible. It was full of strands of gelatinous exudate, forming large solid masses in the lower part. The circulation of the aqueous appeared to have ceased, as the green color of the fluorescein was unchanged in 6 hours and was only slightly diminished in 24 hours after application. In 2 days there was practically no discharge, but the cornea still stained and was more opaque. The surface of the iris looked an almost uniform blood red. At 3 days, there was an attempt at regeneration of the conjunctival epithelium from the limbus and, if this were pigmented, a pigment slide was seen. The staining was not quite complete.

At 4 days, there was no discharge, but the eye was slightly worse. At 5 days, there might be a somewhat moonstone effect as the corneal edema began to increase, but this stage of intense swelling was less the more severely the eye was damaged. Between the 6th and the 8th day, vessels began to invade the cornea, usually first above and below, but soon equally all

around. The center of the cornea still stained and became excessively swollen, unless the eye was very severely damaged. The vessels continued to grow in from the 6th to the 24th day, when they had almost reached the center. In a few eyes, this happened at the 20th day, or might be delayed for 34 days. The arrangement of these vessels was striking. They were long, straight, and radially arranged at right angles to the corneoscleral junction. They were excessively numerous and appeared to naked-eye examination almost like a sheet of blood. As they approached the center, the periphery of the cornea cleared somewhat, and the growing tips only showed as a bright-red ring which contracted as it advanced, appearing to push the edema ahead of it, so that the center of the cornea looked like a conical blue projection in the center of a red circle. This central cone became smaller, and the contracting ring of capillaries was raised into a ridge of advancing granulation tissue, which finally reached the center and projected as a small knot or bleb. As this happened, the central parts showed a gradually diminishing staining area. Finally, the center of the cornea was cast off as a small slough. In some cases, this coincided with the arrival of the ring of granulations at the center, and there was no true perforation. Sometimes, on the other hand, the central slough separated before the vessels had reached it and a descemetocoele, which rapidly perforated, resulted (fig. 10). In either case (granulation or perforation) the eye then rapidly shrank and the vessels narrowed and became less in number, but did not disappear. Perforation or separation of the central slough (fig. 11) might occur at any time from the 19th to the 34th day (earlier in the most severe lesions, as will be seen later). The eye then ceased to stain, shrank, and quieted to a condition of phthisis bulbi. A slight mucocoele

purulent discharge continued the whole time, varying from day to day, but not severe. In $1\frac{1}{2}$ to 2 months, the shrunk eye became pigmented in parts. The limbal pigment ring proliferated, and large, dense, almost black masses of pigment grew on to the cornea in sector-

Lewisite produced necrosis of the cornea before the blood vessels had extended into it. Both lesions were produced by a large droplet. In one case, the rabbit was anesthetized; in the other, it was not anesthetized and was allowed to close the eye at once, thus spreading the Lewisite

Fig. 11 (Mann *et al.*). Stages in the formation of a descemetocoele, seen with the narrow beam of the slitlamp: a, severe edema; b, formation of large fluid spaces; c, perforation only closed by Descemet's membrane.

shaped fringes (fig. 12). The scarred eye became less vascular, and it was often possible to make out, here and there, traces of depigmented iris. There was usually an almost complete anterior synechia, and the pupil was filled with cyclitic membrane. Uveal pigment might be seen on the back of the remains of the cornea. The eye was useless.

(b) Severe lesions which perforate before blood vessels enter the cornea: In 2 eyes of the 12 in the series of very severe lesions the destructive action of the

all over the conjunctival sac. The sequence of events in this eye began with instantaneous intense spasm of the lids, followed by lacrimation in 20 seconds (at first clear tears; in 1 minute and 20 seconds, milky Harderian secretion). In 6 minutes, the third lid was becoming edematous and in 10 minutes, the lids themselves started to swell. The eye was kept closed with occasional blinks. In 20 minutes, the edema was so great that the lids were lifted off the globe and the eye could hardly be kept closed. In 3 hours,

it was not possible to see the cornea, and there were conjunctival petechiae. Laceration continued.

In 24 hours the edema was beginning to subside, and the eye was discharging mucopus. There was a violent iritis, and the cornea was edematous all over in the superficial third. The whole cornea stained. On the 3rd day, there was much discharge, and the lids were stuck together with discharge. There was severe iritis. The cornea was not very swollen.

Fig. 13 (Mann *et al.*). Brawny induration of the lids, discharge and sloughing of the cornea in a very severe Lewisite lesion on the 12th day.

The stain of the day before was still present in the anterior chamber. On the 8th day, there was hypopyon, and the lids were brawny and contracting down on the globe, so that the eye could not be fully opened. No vessels had entered the cornea, which was more opaque. In 10 days, the cornea was still avascular, very opaque, and covered with pus (fig. 13). On the 14th day, the center of the cornea appeared to liquefy and melt away, leaving a descemetocoele which remained intact till the 26th day, when it ruptured, leaving only the remains of an eye in a mass of pus. No attempt at repair or vasculari-

zation took place. The lids and conjunctiva continued to shrink, so that by the 36th day all that could be seen was a narrow discharging palpebral aperture between lids adherent to a disorganized globe.

The course of the lesion in the other eye in this category in an unanesthetized rabbit was similar, the descemetocoele appearing on the 12th day, when this rabbit was killed. Here again there was severe discharge.

These two lesions seem to show that widespread damage to the conjunctiva leads to persistent discharge, failure to vascularize, and to shrinking of the conjunctiva. In the rest of the "very severe" series, the conjunctiva was damaged, but never over so wide an area as in these two.

Many of the rabbits were watched for nearly a year and in no case, was secondary lipoid degeneration and cholesterol deposition observed, so that no condition similar to delayed mustard-gas keratitis was seen, nor seemed likely to occur. The eyes either recovered completely, showed stable scars, or were completely destroyed. The main points of interest were: (i) Peculiar effect on corneal endothelium and corneal corpuscles. (ii) Miosis. (iii) Intense, but transient, edema of lids and conjunctiva. (iv) Intense edema of the cornea, reaching a maximum after the lid swelling had subsided. (v) Characteristic type of vascularization. (vi) Involvement of iris and ciliary body with mesodermal depigmentation and shrinking, and ectodermal pigment displacement. (vii) Effects appear specific for total dose entering eye rather than for anatomical site of lesion.

Nuffield Laboratory of Ophthalmology.

TABLE 1
LEWISITE LESIONS OF VARYING SEVERITY IN 27 RABBITS' EYES

Very Mild	Mild	Severe	Very Severe
No immediate change. Iris flushed in 5 min. ↓ Punctate staining in 1½ hrs. and increased visibility of corneal corpuscles and diamond pattern on endothelium ↓ Opaque corneal corpuscles in 2 days and slight edema ↓ Silkiness 5-8 days. Disappears in a month or less	Pupil contracted in 2 min. ↓ Diamond pattern in 1 hr. Slight edema of lids, 2½ hr. ↓ Cornea staining 1 day. Iritis ↓ "Moonstone eye," 2 days ↓ Subsidence of edema, 6 days ↓ Recovery with fine silkiness, 16 days	Pupil contracted, 2 min. ↓ Diamond pattern in ¼ hr. and edema of substantia propria ↓ Early "moonstone eye." Severe iritis. Deposit on lens, 1 day ↓ Invasion of cornea by vessels, 6 days ↓ Subsidence of edema and retrogression of vessels, 18 days ↓ Recovery with remains of vessels and depigmentation of iris, 3-4 weeks	Contraction of pupil, 2 min. ↓ Severe chemosis and complete corneal haze, 15 min. ↓ Discharge and extreme chemosis, 4 hr. ↓ Chemosis better. Acute iritis 1 day ↓ Invasion by vessels, 6 days ↓ Vessels reach central slough, 20-30 days ↓ Separation of central slough or perforation, 20-34 days ↓ Phthisis bulbi and pigmentation of cornea, 2 months
			Copious discharge, 5 days ↓ Hypopyon, 8 days ↓ Perforation, 14 days ↓ Complete symblepharon and phthisis bulbi, 30 days

MACULAR EDEMA*

ARTHUR J. BEDELL, M.D.
Albany, New York

Edema of the macula may be an isolated condition or part of a general fundus change.

It is universally agreed that the macula varies in size from 1 to 3 mm. in diameter. In or near the center of it is the region of greatest differentiation and specialization. The absence of vessels in the macular region, the foveal depression, and the relatively thick surrounding retina must be considered as determining factors in the appearance of the lesions. Ophthalmoscopically, the macular region is often dark red, and almost invariably the surface changes can be recognized in stereoscopic examination or photographs.

For years, the bright spot seen with the ophthalmoscope in front of the fovea has been called the foveal reflex. It can be proved that the spot is very often absent in a healthy eye with normal, central visual acuity, and also that sometimes the reflex comes from different portions of the vitreous over the same macula in the photographs making a stereoscopic pair. Furthermore, this and the grosser macular reflexes are in front of the retina, vary greatly in visibility, are easily dispelled by a change in the angle of light reflection, and are on the vitreous. When the more delicate lesions, such as foveo-macular disease, are studied, this understanding is essential to interpret correctly the faint changes and the exact placement of each. The macula, although commonly to the temporal side of the disc and slightly below the horizontal level, may be several millimeters above or below its usual location. This is one cause

of head tilting and must be remembered in off-center macular edema. The macula may also be displaced laterally.

Some observers report that they have seen a hole at the macula develop after Berlin's edema. I have not been so fortunate, for, certainly in the usual case of the Berlin type, the edema is transitory and complete functional restoration the rule.

On several occasions I have photographed a circulatory macular destruction from the primary stage of a gray, localized edema, and slight reduction in central vision, through the various phases of infiltration and retinal absorption, until a clear, punched-out, red-based, permanent hole was formed. This type of hole is often smaller than the common, traumatic one, and, eventually, in a high percentage of cases, both eyes become involved.

The hole which results from detachment of the retina or intraocular inflammations may be sharply delimited, or the margins may be soft with an elevated surrounding ring. They may be shallow, suggesting a less complete destruction of the retina; a complete loss, which looks like a red opening in the gray retina; or the margins may form a ridge.

The casual observer may confuse a round mass of exudate in the macular region with either localized edema or a hole. Circumscribed hemorrhages may be incorrectly diagnosed as a hole. The absorption of the exudate, or the blood, will eventually prove the diagnosis. Occasionally, a perfectly round macular scar results from the partial destruction of the retina and choroid.

In sudden occlusion of the central vein,

* Presented at the 15th scientific meeting of the Association for Research in Ophthalmology, Inc., at San Francisco, July 2, 1946.

the retina is very edematous, and frequently an oval-zone embracing the macula is especially prominent. In a branch closure, the edema extends from the closed vein over the macula. The blanched, milky-white edema of an abrupt closure of the central retinal artery is pathognomonic, and the macular red spot varies in size and color.

Stellate edema is characterized either by a circle of exudate spots about the edematous macula, or, and more often, by lines radiating from the macula toward the disc. As the edema subsides, the exudate spots decrease in number and, finally, if the case is observed long enough, they entirely disappear. The edema may be the result of an increased NPN without any other kidney dysfunction, or it may be part of a general hypertension.

In inflammations of the choroid or retina, the edema is often diffuse, covers a large macular surface, is thick, smoke-gray or yellow-tinged, and with or without hemorrhages. As the disease progresses, the edematous region decreases in size and thickness. In the terminal stage, a circumscribed white, plaquelike scar results, with or without pigmentation, and with or without vessels extending to and over it. There are many variations in the amount and disposition of the blood, its manner of absorption, its recurrence, and the association with cystic degeneration. Senile macular degeneration is frequently first observed as a circumscribed cloud of edema.

Another type of macular edema is that found in so-called retinitis circinata, which is not a disease but only a phase of a constantly changing fundus pattern of localized degenerations where a crown of exudate spots, thick, delicate, or even lacelike, surrounds the degenerating macula.

In 1928, I demonstrated photographs of

what we then called preretinal edema. The term is just as appropriate now as then, for it accurately describes the location and appearance of the lesion.

When fluid collects over the macular retina, there is, in the early stages, a demarcating circle or oval of reflection on the pushed-forward vitreous, beneath which the fundus appears dark. The retinal vessels can be traced behind the reflex, and there is no "foveal reflex." As time passes, the reflecting circle enlarges with a corresponding increase in the darker area until, finally, the reflex disappears.

Gifford and Marquardt have called this angiospastic retinopathy but whether this, or central serous retinopathy, or any other term is used, the fundus edema is the same. The disease is said to be limited to young adults. I have seen it in middle and late life.

I have not seen macular drusen nor local holes develop after preretinal edema, which is usually unilateral, rapidly subsides, and leaves few, if any, pigmentary changes. The macular area may appear red, and probably that is the reason why it has been mistaken for a hole. The early vitreous reflex cannot be seen with an ordinary ophthalmoscope.

A Gullstrand or binocular ophthalmoscope or a Nordenson camera is essential, if the earliest signs of macular edema are to be recognized. Errors in diagnosis can be avoided by using red or green filters, reducing the illumination or using indirect illumination, as well as by shifting the light beam from side to side.

There is considerable risk in drawing conclusions regarding any particular therapy for this disease, which is often of short duration and, I believe, uninfluenced by any special treatment.

There are two other conditions which, at times, so closely resemble preretinal

edema that differentiation is impossible without stereoscopic studies or photographs. These are retinal edema and circumscribed retinal detachment.

Macular retinitis may be ushered in by true edema with a large vitreous reflex. This reflex may disappear, be absent some days or weeks, and then reappear, again to disappear as the exudate increases. In this edema, the fundus area is elevated, the retinal vessels are on the surface and can be traced only by stereoscopic examination. The dark-appearing base increases in diameter, as in preretinal edema, until it finally disappears, and the retina assumes its normal color or becomes scarred. The diagnosis of retinal edema depends upon the location of the retinal vessels on the surface of the convex dome of swelling.

Macular retinitis may, however, start with a very slight edema, not to be confused with either the preretinal or retinal edema with ring-shaped light reflexes. From a small, hazy, gray spot, the cloud increases and eventually terminates in a retinal scar. Another type forms a small circle with a pale center and close to it a spot of retinal depigmentation. In some cases, the edema extends from an adjacent, acute exudative retinitis over the macula.

There have been several articles on detachment of the retina at the macula. Idiopathic, flat detachment of the retina has been carefully presented in the thesis of Walsh and Sloan. In any case, where a detachment is suspected, it is necessary to exclude preretinal or retinal edema before reaching such a diagnosis. Here, again, stereoscopic photographs are of great value.

Detachment of the macular retina is very uncommon. Sometimes it is several disc diameters in size and so dark and so prominent that great care must be taken to differentiate it from a malignant

growth of the choroid. Under such circumstances, repeated examinations are obligatory, and no eye should be sacrificed until the diagnosis is firmly established.

In some cases, the subretinal fluid is translucent, so that the outline of the detachment is readily seen. In others, as, for example, in myopia of high degree, a true cyst may partially or completely cover the macula. Some cysts are very small, while others may be more than a disc diameter in size and may be mistaken for a detachment.

The confusion in diagnosis is further increased if the patient is first examined when the condition is subsiding, for in all three—preretinal edema, retinal edema, and macular detachment of the retina—fine white specks, yellow dots, and minute or large pigmentations may develop and persist. These end results depend upon the duration, as well as the severity, of the local reaction, and it is difficult to anticipate or foretell with any degree of accuracy the exact terminal appearance of any given case.

During the past few months, several excellent articles on macular diseases have been published, and I wish to talk about some of them.

Adler and Scarlet, in their interesting paper, presented cases of juvenile macular choroiditis. Such cases are not rare. They are found in both males and females, start without demonstrable cause, follow a prescribed course, last many months, and although the fundus changes seem to vary little from week to week, they are, when carefully observed or photographed, continuous. There is a round, gray edema of the macular region, with some blood and a dark area near the center of the lesion, which, in the beginning, can only be seen with a red light. As time passes, the margin of the circle becomes more defined and the center so much

darker that it is readily seen with the light from any ophthalmoscope. The bleeding ceases, and eventually a circumscribed, round, gray-pigmented scar results. After the outer gray ring is once formed, it rarely increases in diameter. The end result may be a few, pale-gray or dense-black spots, a black ring, or a black center with a white, connective-tissue band across it. The circumscribed area, the uneven surface, the protracted course, and the recurring flat, granular hemorrhages are dominant characteristics of this type. Usually unilateral and occurring in young adults, I have, however, seen it in both eyes in late life.

The critical analysis of central visual impairment reported by Cordes for the group of Navy ophthalmologists is not only comprehensive and well done, but also thought-producing, for it stimulates all ophthalmologists to be accurate in the recognition of small deviations from the normal and correct in their interpretations.

Some months ago, before the Cordes report, I talked with him and said that I had been seeing peculiar macular lesions in young adults in the Army, as well as some officers in the Navy who had been in the earliest South-Pacific campaign. It is unfortunate that photographic records were not kept for patients in the European theater.

In the Cordes report, it is noted that, in certain types of trauma, there is a partial destruction of the macular region. The outline of the reddish area is indefinite, as it fades into the surrounding, normal-appearing retina, and looks like an incomplete hole. On closer inspection, the lesion is found to be a puckered scar, the apex of which is white and elevated, suggesting an accentuated, so-called foveal reflex.

In other cases, the macula is red and slightly depressed, showing a genuine,

superficial, partial destruction of the retina.

The study of complicated fundus patterns frequently leads to the correct interpretation of local changes. In a case of traumatic macular retinochoroiditis with retinitis proliferans, delicate hemorrhages were seen in the proliferans, as well as a pink spot which looked like a small hole in the retina. This was easily proved to be an opening in the proliferating sheet through which the red fundus background was visible. It is not improbable that some reported cases of hole at the macula may come under this group.

As an example, the same suggestion of a macular hole was found in the left eye of a young soldier whose fundus I had photographed and found normal before he entered the Service. He had recently noted a marked reduction in vision. To the outer side of the macular region was an elevated, gray layer with an almost circular, pink center, which was the retina seen through the overlying vitreous edema. When the acute stage subsided and the gray edema of the vitreous had disappeared, there were several pigmented granules over what had been the pink spot.

Most of the Service-connected cases, as well as those in civilian life, have been unilateral. The etiology is unknown.

SUMMARY

The common causes of edema of the macular region have been demonstrated.

Special attention has been drawn to Berlin's edema, the various causes for holes at the macula, and the inflammatory reactions of retinochoroiditis and retinitis.

In hemorrhagic exudate or traumatic hole, it is very probable that there is always some edema at some time, and, for that reason, examples of each are included.

Preretinal and retinal edema have been explained as a pushing outward of the vitreous, producing the ring-shaped light reflex which is on it.

Some of the recent papers on macular edema have been referred to, and additional illustrations of juvenile macular degeneration, central serous retinopathy, local detachment of the retina, and foveo-macular diseases have been presented.

CONCLUSIONS

An edema of the macular region may

be the isolated expression of a local or general tissue reaction. The edema may be limited to and disappear from the macula, or it may be the precursor of an extensive retinochoroiditis or gross macular change. The healed macula may show pigmented specks, white dots, heaped-up pigment, atrophy, or thick scars which may be smooth and flat, or rough and nodular.

This essay was illustrated by a series of Kodachrome photographs.

DISCUSSION

DR. RALPH I. LLOYD (Brooklyn): Will you give an idea of the apparatus used in making the diagnosis of this group of fundus lesions?

DR. BEDELL (closing): The diagnosis of all fundus lesions is made by the use of

the ordinary ophthalmoscope with red, green, and yellow filters and the Norden-son camera. The finest diagnostic detail is seen with the Nordenson and confirmed by the study of stereoscopic Kodachrome photographs.

THE RELATION BETWEEN MATERNAL VITAMIN-A INTAKE, BLOOD LEVEL, AND OCULAR ABNORMALITIES IN THE OFFSPRING OF THE RAT*

BLANCHE JACKSON, PH.D., AND V. EVERETT KINSEY, PH.D.
Boston, Massachusetts

The experimental production of congenital eye lesions by means of maternal vitamin-A deficiency has been demonstrated in several animal species. The literature on this subject has been reviewed recently by Warkany.¹

In the rat, the eyes of offspring born by vitamin-A-deficient mothers may show abnormalities resembling in some respects the condition of retrolental fibroplasia as found in man. The following eye defects are some of those described by Warkany and Schraffenberger as appearing in the rat: absence of anterior chamber, iris, and ciliary body; failure of vitreous formation, with the development in its place of connective tissue; eversion of the retina, and retinal disorganization.^{2, 3} These workers observed considerable variation in the degree of abnormality occurring in different litters. In some instances, the defect consisted only in the development of a retrolenticular mass of connective tissue.

The object of the present investigation was to attempt to repeat Warkany and Schraffenberger's findings and at the same time to determine the degree of the deficiency in the mothers which will lead to ocular maldevelopment.

EXPERIMENTAL PROCEDURE

Albino rats of the Sprague-Dawley strain were used. The Warkany procedure was followed in the first three experi-

* From the Pathology Laboratories of the Massachusetts Eye and Ear Infirmary and the Harvard Medical School. Presented at the 15th scientific meeting of the Association for Research in Ophthalmology, Inc., in San Francisco, July 2, 1946.

ments by placing female weanlings on a basal vitamin-A-deficient preparatory diet (Warkany's diet U¹)† supplemented with vitamin D and with carotene sufficient to allow growth and sexual maturation, but insufficient to allow the accumulation of significant hepatic stores. To mate the rats during the working day, their diurnal rhythms were reversed; this was accomplished by keeping them in rooms with reversed periods of light and dark. During this preparatory period, the animals were housed in large cages provided with wire-mesh floors; about 10 rats were kept in each cage. When the females were 90 to 100 days old, they were transferred to individual cages and fed a purified diet deficient in vitamin A (Warkany's diet W²).‡ Following Warkany, each animal received an oral dose of 50 I.U. of vitamin D, 2.5 mg. of α -tocopherol, and 10 micrograms of 2-methyl naphthoquinone every 10 days. Crystalline carotene (Smaco) dissolved in Wesson oil, or vitamin A, was administered orally as indicated in the separate experiments. For the mating of these females, healthy male rats of the same strain were used. In most instances, the time of mating was determined within a few hours by the presence of a vaginal plug or sperm.

Blood samples used for vitamin-A determination were obtained from the tail

† Percentage composition of Warkany and Schraffenberger's preparatory diet: Ground whole wheat, 74; crude casein (Borden), 15; brewers' yeast (Mead Johnson), 10; sodium chloride, 1.

‡ Percentage composition of Warkany and Schraffenberger's purified diet: Sucrose, 68; vitamin-test casein, 18; vegetable oil, 10; salt mixture, 4.

vein at least 20 hours after the administration of any vitamin-A supplement. When a sample was taken just prior to killing the animal, it was obtained by cardiac puncture. Vitamin-A analyses were made on approximately 0.1 ml. blood serum, according to the micro-method developed by Lowry and Bessey.⁴

First experiment. The first experiment was designed simply to reproduce Warkany's experiments. Fifty-seven female rats 25 days old were placed on the preparatory diet. They received 25 micrograms of carotene on the 34th, 44th, and 54th days of age. Because the animals showed more rapid growth than Warkany's,* the carotene supplement was then discontinued. On the 89th day, animals showing marked signs of vitamin-A deficiency were placed on the purified diet supplemented with one or two doses of 25 micrograms of carotene. On the 93d day, the remaining animals were transferred to the purified diet, and mating was begun. At this stage, many of these animals showed severe signs of vitamin-A depletion. The fur was dirty and stained, there were deposits of reddish material (porphyrin?) about the eyes, and the eyes showed the xerophthalmia characteristic of vitamin-A deficiency. Some animals exhibited respiratory difficulty. Nine rats died at 91 to 110 days of age, before being mated; at autopsy several were found to have kidney disorders involving infection, enlargement, and/or stone formation. To prevent more deaths, a maintenance dose of vitamin A (20 I.U. orally about every 10 days) was given to the

remaining rats during the period of mating and gestation.

Thirty animals were mated shortly after the diet change, and of these, 20 became pregnant. Five of the pregnant animals died within three weeks after mating. At the time of death, two of these had completely resorbed their fetuses; three had fetuses 18 to 19 days old which could be used for histologic examination. Six pregnant animals were killed 14 to 24 days after mating; five had fetuses in various states of resorption; one, however, had eight live 21-day old fetuses which could be used for histologic study. The other nine pregnant rats resorbed their litters. Thus, from 57 animals, fetuses in an advanced state of development were obtained from but four mothers.

Terminal vitamin-A analyses were made on two of the four animals which carried their young nearly to term. In both instances, the serum vitamin A was less than 5 I.U. per 100 ml. (the normal blood serum vitamin A for mature female rats of this strain is about 75 I.U. per 100 ml.) Further evidence that this is a vitamin-A deficiency is seen in the weight response of the animals to small doses of vitamin A (fig. 1).

The eyes of the young in all four litters exhibited ocular abnormalities essentially similar to those described by Warkany. Complete serial sections of the two eyes of one fetus from each litter were made, in addition to nonserial sections on two or three other members of each litter. In every instance, there was a retrolental mass of connective tissue; in the eyes from three litters it extended from the lens to the region of the nerve head. In all except one animal, there was marked retinal folding. In several eyes, there was slight retinal eversion near the nerve head. In one specimen (18-day), the fetal fissure had failed to close at any point. Large hemorrhages in both the primary

* This apparent discrepancy in growth rates was clarified by correspondence with Dr. Warkany. The original value cited in his first paper was a numerical error, since 4 micrograms instead of 25 micrograms of carotene were given every 10 days.

optic vesicle and the vitreous space were found in the eyes from two of the litters. Sections made from one of the abnormal eyes are shown in plate I. These abnormalities appear to be somewhat less severe than those studied by Warkany. For

spring. The animals used were a group of the original lot employed in the first experiment—those which were still unmated after several weeks on the purified diet and those which had resorbed their first litters. The animals were separated into

example, there were no cases of young carried to term with the "open eyes" which Warkany and Schraffenberger described.

Second experiment. The object of the second experiment was to determine the maximal daily dose of vitamin A which, when given to females depleted of their vitamin stores, would result in development of eye abnormalities in the off-

groups and given daily doses of 2, 3, 5, or 10 I.U. of vitamin A daily.

The general condition of the animals in this experiment was superior to that in experiment 1. Moreover, they showed a more uniform physical state through the experimental period, presumably because they received vitamin A daily, rather than at 10-day intervals. Marked symptoms of ill-being were noted only at the end of pregnancy and seemed to be related to

difficult parturition or inability to deliver.

From the mothers receiving 2 I.U. of vitamin A daily, only one mature fetus was obtained. This fetus had normal eyes. The serum vitamin-A level in the mother on the 22d day of pregnancy was 24 I.U. per 100 ml.

Three litters were obtained from moth-

A per day were studied histologically. One of two fetuses sectioned from one litter showed abnormal retinal folding in the upper portion of one eye and a coloboma. One specimen from another litter also exhibited retinal folding and slight eversion of the retina. The four members of the other two litters studied had nor-

Plate I (Jackson and Kinsey). A, B, and C are transverse sections taken approximately one third, one half, and two thirds from the top of the eye, respectively, of an abnormal fetus about 19 days old. Sections D, E, and F are from a normal 19-day rat fetus.

ers receiving 3 I.U. daily. Of six fetuses in one litter, three had ocular abnormalities, including an orbital cyst (one case), retinal folding, and retrolental connective tissue. In the second litter, of four fetuses sectioned but one showed any abnormality, and this consisted only of retinal folding. Three of the eight young in the third litter were sectioned, and all three were found to be normal. The abnormalities consisted of retinal folding and retrolental masses of connective tissue, as may be seen from plate II. Serum vitamin-A levels of the three mothers in this group, taken at various times during pregnancy, ranged from 0 to 12 I.U. per 100 ml.

The eyes of four litters carried to term by mothers receiving 5 I.U. of vitamin

mal eyes. Serum vitamin-A values for these mothers on the 21st to 22d day of pregnancy ranged from 6 to 21 I.U. per 100 ml.

Three mothers receiving 10 I.U. per day produced young with normal eyes. Serum samples collected from the mothers 9 to 22 days after mating gave a range of 12 to 54 I.U. of vitamin A per 100 ml., the average being 35 I.U.

The results of this experiment indicate that ocular abnormalities are obtained from rats previously depleted of vitamin-A stores only when the dose of vitamin A does not exceed 3 to 5 I.U. per rat per day. Furthermore, the degree of abnormality appears to be related inversely to the daily intake, so that at the 5-I.U. level,

except for one case of coloboma, only abnormal retinal folding was observed.

Third experiment. In the previous experiments, the yield of mature live young with severe ocular malformations was very low. In addition to the high percentage of resorptions, many young died be-

the weanling stage were placed on the preparatory diet and given 12.5 micrograms of carotene every 10 days. The final dose before the change to the purified diet was double this amount. At the time the animals were put on the purified diet, daily supplements of 1 or 2 I.U. of vitamin A were begun. Control animals

Plate II (Jackson and Kinsey). A, B, and C are transverse sections through an abnormal eye of a mature (22-day) rat fetus. Sections D, E, and F are from a control rat killed at birth (22-day gestation period).

cause the mothers were too depleted to deliver them. Since Warkany and Schraf-fenberger had observed the eye defects as early as the 15th day of fetal life, it was thought that the abnormal young might be carried to term and delivered by the mothers maintained on low vitamin A until the 15th day and then given adequate amounts of the vitamin. A second approach to the problem was suggested by Mason's finding that the resorptions occurring in vitamin-A deficient rats are indirectly associated with bacterial infection.⁵ In an attempt to offset this occurrence, the mothers were treated with sulfathiazole and with penicillin.

Two groups of rats were used for these experiments. In the first, 36 animals in

(five) were given 100 I.U. daily. On the 15th day after mating, the daily supplement to the low vitamin-A group was increased to 100 I.U.

Only one mature fetus was obtained for histologic examination, and this was taken by Caesarian section. It did show, however, the characteristic eye abnormalities. Analyses of the mother's serum vitamin A on the 0, 5, 10, and 15th days of pregnancy gave values of 12, 11, 5, and 10 I.U. per 100 ml., respectively. Somewhat higher values were obtained on other animals which resorbed their litters completely and at an earlier stage of gestation. Control animals delivered normal, live young.

The second group of animals received

12.5 micrograms of carotene throughout the preparatory period. They, too, received daily vitamin-A supplements of 1 or 2 I.U. after being changed to the purified diet. Some of the animals received sulfathiazole at a 1-percent level in the food for the first 15 days after mating. Others were injected with penicillin (500 Ox. u. in 0.1 ml. of vegetable oil) twice daily on the 8th through the 12th day after mating. On the 15th day of pregnancy, the mothers were changed from the purified diet to a commercial stock ration.

No full-term fetuses were obtained from the mothers kept on low levels of vitamin A during the first two weeks of pregnancy. Analyses of 19 blood samples collected during the first 15 days of pregnancy from seven mothers which resorbed their litters showed the average serum vitamin A to be 6 I.U. per 100 ml. (range 0 to 20). The average of 12 determinations on similar samples from five control animals was 51 I.U. (range 28 to 81).

Fourth experiment. In still another attempt to obtain live young showing eye abnormalities, female rats were allowed to grow normally to maturity on a complete stock ration and then depleted of their vitamin-A stores to varying degrees. The animals were put on the Warkany purified diet at 110 days of age. After periods of 5 to 13 weeks, they were mated. To keep the blood-vitamin-A level at a relatively constant value during the early period of pregnancy, some of the animals were given 1 or 2 I.U. daily. As in the previous experiments, additional vitamin A was supplied on the 15th day after mating. In the present experiments, this was accomplished by placing the animals on the commercial stock ration.

Complete data on this group are given in table 1. It will be observed that, from the 135 live young born, none showed

the eye abnormalities described by Warkany and Schraffenberger, although in two instances some retinal folding was observed (Nos. 169 and 190). The occurrence of this condition was probably related to the fact that the mothers of these two litters were severely depleted of vitamin A. In general, only essentially normal young were carried to term; mothers very low in vitamin A resorbed their litters. If the number of mothers depleted to such low levels associated with fetal resorptions had been greater, it is possible that a small percentage of abnormal litters might have been obtained.

DISCUSSION

Results cited previously have indicated that the ocular abnormalities occur only with daily vitamin-A allowances of less than 3 to 5 I.U. It is important to correlate the ocular defects with the various serum levels of vitamin A which were taken from time to time throughout the period of pregnancy. In all the animals producing young with abnormal eyes, the serum vitamin-A levels were less than 12 I.U. per 100 ml.; normal eyes were obtained when the maternal-serum vitamin-A level was only slightly greater than this. Thus, ocular defects occur in the young of rats having serum levels approximately one tenth or less of the normal.

It is worth noting that no vitamin-A deficient mothers seemed to be able to deliver their abnormal young. Although some defective fetuses may be carried to term, the amount of vitamin A required for successful parturition seems to be beyond the range of that associated with the production of ocular abnormalities.

Warkany and Schraffenberger reported that the vitreous was lacking in the abnormal eyes, the space which it would normally occupy being filled with the retrolental connective tissue. Although we

TABLE 1
DATA ON NUTRITIONAL EXPERIMENTS ON 19 FEMALE RATS

No.	Days on Deficient Diet at Mating	Daily Vit.-A Supplement, Days 0-15 of Pregnancy	Serum Vit. A—I.U. % Days after Mating					Notes on Pregnancy	Eyes of Offspring

* Put on Rockland rat pellets on 15th day of pregnancy.

† In addition to being changed to commercial rat pellets on 15th day, No. 190 received 100 I.U. vitamin A per day on days 15-23.

‡ No. 169 was maintained on the purified diet without any vitamin-A supplement throughout pregnancy.

also observed eyes where this occurred, in some instances the retrolental mass was considerably reduced and vitreous was present. This would appear to represent

one of the variations in degree of the effects produced by the vitamin-A deficiency.

Marked folding of the retina (or inner layer of the optic cup) is one of the most striking features observed in the abnormal eyes. In some cases, it reduces considerably the space which in normal eyes is occupied by the vitreous body. In many eyes, the folding seems to be definitely the result of overgrowth of this layer, a condition which could lead to the retinal eversion frequently observed. Retinal folding, especially in the upper part of the eye, seems to be the first abnormality encountered as one goes from completely normal eyes to those of increasing degrees of malformation.

SUMMARY AND CONCLUSIONS

Following techniques devised by Warkany and Schraffenberger, a group of 57 weanling female rats were grown to maturity without the accumulation of hepatic stores of vitamin A. They were then bred and given only minimal amounts of vitamin A during pregnancy. Four of the mothers carried their fetuses to advanced stages of development. The eyes of the young in these litters showed the abnormalities which have been described by Warkany and Schraffenberger.

To determine the limiting level of vitamin-A dosage in female rats producing young with abnormal eyes, similarly pre-

pared female rats were given 2, 3, 5, or 10 I.U. of vitamin A daily. They were then bred, and the supplement was continued at the same level. Young obtained from mothers fed less than 3 to 5 I.U. daily showed the eye defects already mentioned, whereas those receiving more than this amount of the vitamin all had normal eyes, even though the vitamin-A dosage was insufficient to allow normal delivery in many cases.

Serum vitamin-A values, taken during pregnancy from female rats producing young having abnormal eyes, were found to be less than 12 I.U. per 100 ml. in every instance (normal, 75 I.U. per 100 ml.). The addition of 100 I.U. of vitamin A daily or the feeding of a stock ration after the 15th day of pregnancy, with or without treatment with penicillin or sulfathiazole, did not reduce the high percentage of fetal resorption observed in the previous experiments.

It is concluded that ocular defects occur in the young rat only when the maternal vitamin-A deficiency is extremely severe, so advanced, in fact, that fetal resorption is common and normal birth is impossible.

To the extent that the physiologic processes associated with reproduction in human beings parallel those in the rat, it may be inferred that vitamin-A deficiency in the mother is not a probable cause of retrolental fibroplasia.

DISCUSSION

DR. CONRAD BERENS, chairman (New York) : This is a piece of research which is so vital in the prevention of blindness. We know that about 51 percent of blindness in the schools for the blind is caused by congenital abnormalities.

DR. DERRICK VAIL (Chicago) : Were there any skeletal malformations, especially in the optic foramen, base of skull, and so forth, observed?

DR. V. EVERETT KINSEY (Boston) : We have not yet examined the eyes or the animals for other defects including skeletal abnormalities, so I am unable to answer that question. Warkany, I believe, has described such defects in detail.

DR. VAIL : I should like to say just a few words, if I may. I want to inject here a note of warning. A few weeks ago, I testified in a criminal court case brought against a quack vitamin specialist who cited experimental work, reported in Iowa, on vitamin-D deficiency as a cause of anophthalmos in a litter of new-born pigs.

In his pamphlets, broadcast widespread to the public, he used the reports of these experiments to terrify pregnant women and urged them to buy his vitamin product as a prevention of blindness in the unborn child.

I should like to have, some place in the discussion, a firm statement to the effect that the results of your experiments are not yet applicable to human beings.

DR. KINSEY : I think our conclusion was to the effect that, in so far as the physiologic processes were the same in rats and in human beings, vitamin-A deficiency is not a probable cause of retrolental fibroplasia.

Even though we have to change our minds, I think, for the record, it might be well to be over cautious and say definitely that these results do not suggest that maternal vitamin-A deficiency is in any way associated with ocular abnormalities in infants.

DR. T. L. TERRY (Boston) : It is not intended to detract from this presentation, but I think it would interest you to know that pediatricians working on the problem of retrolental fibroplasia found clinically that this abnormality, which Jackson and Kinsey have reproduced, has developed in two infants whose vitamin-A blood level was kept normal by therapeutic measures. It may interest you further that, according to Clifford and Allers, vitamin A, when dissolved in oil, is not absorbed by the premature infant from the gastrointestinal tract, nor is it absorbed following subcutaneous or intramuscular injection. If the vitamin A is dissolved in glycerol instead of oil, they found that the level of the vitamin in the blood is elevated. In two infants who had received such injections, retrolental fibroplasia developed despite normal vitamin-A levels in the blood.

INTRAOCULAR MANIFESTATIONS OF ACUTE DISSEMINATED LUPUS ERYTHEMATOSUS*

REPORT OF A CASE

FERDINAND L. P. KOCH, M.D.

New York

AND

(BY INVITATION)

WILLIAM P. MCGUIRE, M.D.

Winchester, Virginia

The paucity of adequate descriptions of the eyegrounds in instances of acute disseminated lupus erythematosus, with the exception of Maumenee's contribution, appears to be rivaled only by the infrequency with which such pertinent observations accompany reports of this disease in the medical literature. It is hopefully anticipated that an entity exhibiting such protean manifestations of a vasculo-allergic character be the subject of the integrated attention of the ophthalmologist, the internist, and of the dermatologist, each of whom, within his special field, encounters deviations from the normal. Many of these are exemplified in the following condensed case report.

B. L., an unmarried Jewess, aged 22 years, and of asthenic habitus, was admitted to the Presbyterian Hospital in October, 1938, with a history of recurrent fever and malaise for the preceding six weeks. She had had, however, frequent, migratory, multiple joint pains, chronic

pharyngitis, cervical adenopathy, leucorrhea, and intermittent fever during the two years since October, 1936, in which month the differing diagnoses of septic sore throat and scarlatina had been made by local physicians. Infectious arthritis also had been considered. There had been one bout of severe erythema of diffuse distribution of four to five days' duration six months prior to the patient's admission. The rash and temperature had subsided simultaneously. Exacerbations, however, tended to recur with the advent of cold weather and were accompanied by weakness and anorexia. General examinations, as well as symptomatic treatment by numerous local physicians, consistently yielded essentially negative results. Her past history was otherwise irrelevant.

A questionable systolic murmur at the apex, normal blood pressure, enlargement of a small tender lymph node in the right axilla, a thick malodorous leucorrhea, and a virginal introitus were the only positive findings on general physical examination at the time of admission to the Hospital. All of the indicated special examinations were made: X-rays of the chest, abdomen, viscera, and skeleton were negative; agglutination tests for hemolytic streptococcus (group A), typhoid, typhus, paratyphoid, and brucellosis were negative as was the Frei test; specific allergy testing was not undertaken, but intracutaneous testing for brucellosis and tuberculosis yielded

* From the Departments of Ophthalmology, Bellevue Hospital and New York University. Manhattan Eye, Ear and Throat Hospital. Presented at the eighty-first annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, November, 1945.

negative results. There was mild hypochromic anemia with moderate leucopenia (relative) and slight hemoglobinemia; no parasites were found in the blood or stool, and blood cultures were negative; serum protein was very slightly reduced, and there was a moderate hyperglobulinemia. The results of blood-chemistry tests were otherwise normal. Sedimenta-

Fig. 1 (Koch and McGuire). O.D. drawing, February, 1939.

tion rate was 54 mm. in the first hour; urinalysis revealed slight albuminuria; and biopsy examination of the enlarged right axillary node revealed a mild nonspecific lymphadenitis, with no bacterial growth on culture.

The course under hospital and convalescent home care, until the patient's death on September 25, 1939, was essentially one of remissions and exacerbations of muscular and joint discomfort, elevation of the temperature to an occasional high level of 104°F., but of no characteristic type, upper respiratory infections and bronchopneumonia, maculopapular erythema of irregularly diffuse distribution, maintenance of normal diastolic and systolic blood pressures, abdominal pain with tenderness and spasm, mental irritation, and increasing apprehension as discomfort and diminishing vision progressed.

By gradual exclusion the clinical diagnosis of acute disseminated lupus erythematosus was decided upon approximately three months after the patient was admitted to the hospital. Laboratory findings, on frequent examinations, were somewhat variable, but the general trend during her illness continued to be one of increasing deviations from the normal in the directions indicated on the first tests performed after admission. The exception to this was the continued variability of the Kline and Wassermann reactions no matter what antigen was employed. Treatment included all suggested symptomatic aids, physiotherapy, sulfonamides, and the customary antisyphilitic agents, any one or all of which may have been without effect or may have initiated remissions or exacerbations. Autopsy permission was refused by the male parent.

Ophthalmoscopically, no observations were made except by the medical house officer (who reported the fundi normal on admission) until a complaint was made of blurred vision during an exacerbative bout of temperature elevation and discomfort. Then another medical house officer, three months after admission, thought that there was a haziness of the disc, nasally, but that the fundi otherwise seemed negative. Previously, shortly after admission, the medical resident had made a note of the conjunctival injection and the redness and edema of the lids.

Ophthalmologic examination was requested 3½ months after admission, after which there were periodic consultations by several observers, and fundus drawings were made. It was found on this first examination (fig. 1) that both optic discs were equally normal in color and demarcation and structurally were normally full. The fovea of the left eye and the macular areas of both were distinguishable as such. In general, the retinopathy found in the left eye was similar

to, but not so advanced as, that observed in the right. Here, numerous fine to larger, superficial hemorrhages of all types were seen in the relatively avascular macular and peripheral retinal areas as well as in other places where the retinal circulation was not obviously abundant. These hemorrhages, furthermore, were in close proximity to capillaries and to the smaller venules and arterioles, especially the former. There was marked periphlebitis slightly temporal to, and in the far periphery above, the disc. Segmental periphlebitis on a lesser scale was observable in the extreme peripheries, chiefly in the temporal quadrants. The general impression of a severe vasculitis was heightened by the presence of somewhat deep retinal and more superficial choroidal, roundish, gray-white exudates, the distribution of which was more irregularly diffuse than that of the hemorrhages. A group of older, partially absorbed exudates in the macular area was situated so deeply that it was believed they had their origin in the relatively lush vascular areolar area of the choriocapillaris. The general ophthalmoscopic impression recalled previous observations of such diffuse disease entities as periarteritis nodosa and, less typically, dermatomyositis.

Subsequent examinations revealed progressive intensification, but on a more extensive scale, of the retinopathy just described; however, the changes in the left eye continued to be proportionately less marked than those in the right. The vasculitis became more widespread and progressed proximally toward the disc; hemorrhages and exudates became more numerous but there continued to be some absorption of those previously present. One large subhyaloid hemorrhage occurred superiorly in the right eye but was absorbed within a few weeks, and a large oval hemorrhage nearly the size

of the disc appeared in the upper macular area in this eye. There occurred progressive obliteration of the lumen of the more peripheral retinal vasculature with complete replacement fibrosis manifested by yellowish-white connective-tissue cords traversing the original vascular channels and shading fairly abruptly into the still patent, more proximal vessels whether

Fig. 2 (Koch and McGuire). O.D. drawing, June, 1939.

venous or arteriolar. There was primary optic atrophy in the right eye eight months after admission, when the second drawing was made (fig. 2) but this phenomenon still was in progress of development one month later in the left eye (fig. 3). The eyegrounds in general became mildly anemic in color.

Subjective ocular testing was not feasible because of the patient's discomfort and her lack of sustained coöperation, nor could additional drawings be made. As debasement of the general clinical findings progressed, further intensification of the described retinopathy occurred, and, although the changes in the left eye continued to lag somewhat behind those observed in the right, the conversion to fibrosed cords of previously normal vascular channels continued together with increasing optic-nerve atrophy and gradually decreasing hemorrhaging and exu-

dation. The retina became thinner, but the increase of diffuse, fine, granular, retinal pigmentation permitted no visualization of the choroid. Prior to death, light perception was lost in the right eye and was barely elicitable in the left. The media remained clear in each eye.

DISCUSSION

Speculation on the central etiology in this case with its widespread clinical

Fig. 3 (Koch and McGuire). O.S. drawing, July, 1939.

manifestations remains speculation in the deplorable and unfortunate absence of post-mortem examination; however, it is of interest to consider the opinions of two groups of observers in this connection. Klemperer, Pollack, and Baehr, recalling the thesis of Morgagni that diseases reside in certain organs, point out that we recognize the interdependence and unity of certain organs to form organ and tissue systems, and that entities such as acute disseminated lupus erythematosus and diffuse scleroderma, among others, may reasonably be considered as systemic diseases of the connective-tissue system with fibrinoid degeneration of the collagenous fibers and ground substance. These authors, although granting the possibility that fibrinoid degeneration of

collagen may result from hyperergic inflammation, do not believe that this type of degeneration always indicates a state of hypersensitivity. They feel that further investigation of the colloid system and its colloidal status must be made by biophysical and chemical methods.

The recent excellent review on the lupus-erythematosus concept by Stokes, Beerman, and Ingraham, Jr., stresses, on the other hand, the application of the "id" conception (tuberculids, syphilids, follicular "ids," *et cetera*) as that of allergic inflammation with its sequelae and homologies. Thus, it is suggested that "dissemination of a discoid or follicular erythematosus lupus (a lupo-erythematosid?) with the appearance of desquamative patches with follicular atrophy over other parts of the body, is simply an extension of the follicular 'id' beyond its conventional locus, under conditions affecting the general allergic state of the individual." Exacerbation and generalization may occur as the allergic base is broadened by some influence such as sulfonamide therapy or tuberculin skin testing or the physical allergen of actinic rays. If these allergic manifestations, or "id"-like processes, remain confined to the skin itself, the prognosis is not grave because of the well-known benignity of the disseminating discoid type of the disease. The reviewers then state: "*On the other hand*, in the hypersusceptible person—the infection-allergic type of individual, let us say—the epidermo-allergic or folliculo-allergic type of reaction that underlies the chronic discoid process may at a suitable provocation pass over (though only occasionally) into the field of vasculo-allergic manifestations and assume the far graver characteristics of the so-called acute disseminating type of the disease."

Thus, as they so succinctly point out: "The vasculo-allergic type of 'lupus ery-

thematosis' then, may be preponderantly local and cutaneous in its manifestations, or preponderantly systemic (fever, lymphadenopathy, leukopenia, absolute or relative, with or without thrombocytopenia, and with demonstrable vascular lesions, of the eyes, kidney and endocardium). It may be acute or chronic, or both. It may be combined with follicular 'id' lesions of discoid type and distribution, or not. The systemic vasculo-allergic lesions may come to notice first and dominate the picture to exitus." The reviewers strongly imply, moreover, that they are not in agreement with those dermatologists who believe that the absence of skin lesions is not uncommon and it is implied that a thorough search will not fail to reveal typical cutaneous lesions in this systemic disease.

In this connection, it is our opinion that early and thorough ophthalmoscopic examination is strongly indicated in all instances of "fever of unexplained origin" (one of the synonyms for acute disseminated lupus erythematosus) in pale, sickly, weak, asthenic women in their menstrual years. There also may be light sensitiveness, febrile episodes, with or without leucopenia, cutaneous petechiae, thinning hair, puffiness, and redness of the lids, arthritoid disturbances with re-

lief of pain by salicylates but with no corresponding temperature decline, and pleural, endocardial, and pericardial signs and symptoms but with negative blood cultures.

Few males, and then only in the years between puberty and early middle age, develop this disease. Stokes and his co-reviewers as well as the Mayo Clinic group hold pessimistic views concerning the effect of treatment of this condition; however, the former have discussed cautiously the possible benefit to be derived from induced menopause as considered by Rose. Indiscriminate but well-intentioned chemotherapy as a cause of exacerbation of a concealed systemic focus of infection might reasonably be avoided to some extent if early ophthalmoscopic examinations were made routinely whenever this type of disseminated erythematosus was suspected. It is our opinion that, although elevation of systemic blood pressure may ensue because of the nephritis present, the ophthalmoscopic differentiation between, or the coexistence of, the lupus and the hypertension should not be impossible if the intraocular findings, as indicated in this report, are considered as vasculo-allergic manifestations of widespread systemic, diffuse collagen disease.

NUTRITIONAL AMBLYOPIA IN AMERICAN PRISONERS OF WAR LIBERATED FROM THE JAPANESE

SAMUEL M. BLOOM, MAJ. (MC), A.U.S., EARL H. MERZ, MAJ. (MC), A.U.S.,
AND WILLIAM WICKHAM TAYLOR, CAPT. (MC), A.U.S.

Phoenixville, Pennsylvania

The purpose of this paper is to present the clinical picture of American soldiers liberated after an extended confinement in Japanese prison camps under conditions of severe malnutrition. The study was done on 33 soldiers captured in April and May, 1942, on Bataan and Corregidor, and liberated in early 1945. The development of early symptoms and findings was observed by one of us (S. M. B.) while a prisoner in Cabanatuan. The final and residual findings were observed by the other two collaborators while the patients were hospitalized in an Army eye center in the United States. During the period from liberation to arrival at this Eye Center, the patients had received an adequate diet and supplemental vitamin therapy and had returned to approximately their normal weight.

OBSERVATION OF PRISONERS OF WAR IN THE PRISON CAMP

Beginning in May, 1942, the survivors of the American forces of Bataan and

Corregidor were subjected to living conditions which led to malnutrition, various vitamin deficiencies, and starvation in the Japanese prison camps in the Philippines.

In the main, the diet consisted of about 300 gm. of polished rice plus a thin soup made of low-grade vegetables and weeds. Negligible amounts of fruit were occasionally furnished. Meat was almost completely lacking. Rarely, one pig would be furnished for a group of 2,500 men. After dressing and cooking, about all that would appear in the soup would be a bit of the hide and a few shreds of meat.

During the first four months of imprisonment, the men developed beriberi (both the wet and dry types), scurvy, pellagra, ariboflavinosis, and xerophthalmia, to mention a few of the clinical syndromes apparent. Naturally, the picture was that of a mixed avitaminosis in most cases, with one or other of the manifestations predominating. In addition, malaria, dysentery (amebic and bacillary), and diphtheria affected many. Of about 6,500

in Cabanatuan, 2,700 men died in the first year.

Blurring of vision began insidiously. It was first reported in September, 1942; that is, after about four months of starvation diet. The impairment of vision was described by most of the patients as an intermittent fading, more marked in bright sunlight. This process was gradual, and went unnoticed by many. After two to four weeks, retrobulbar pain and burning sensation in the eyes appeared in attacks during the later afternoon of bright sunny days, or during the early evening. These attacks were accompanied by photophobia and lacrimation. At that time, examination usually revealed no external gross alteration of the eyes; but in a few instances, mild injection of the conjunctiva was present. No visual test charts were available nor materials with which to make them; no lenses, no ophthalmoscopes, and practically no medicines, so that examination and treatment were extremely limited.

In October, 1942, the attacks of burning in and behind the eyes became more marked. It was then that the cornea was noted to be dry and roughened. After another day or two, superficial ulcers appeared. These were mostly round or oval in shape, over the pupil or lower half of the cornea, and usually single. Circumcorneal injection became evident. Unfortunately, no fluorescein or other staining drug was available at the time. In most cases, there was little infiltration of the cornea. Small amounts of cod-liver oil were obtained, and it was found that the ulcers healed after 4 to 10 days of its administration. However, the impaired vision persisted and, in most cases, progressed. A few of the corneal ulcers went on to perforation, or were complicated by hypopyon and iritis.

In November, 1942, a change of Japa-

nese administration brought an increase in the ration. Rice was increased to 400 gm., meat to 50 gm., and squash and comotes (a variety of sweet potato) were added. For the eye patients, 4 oz. of evaporated milk, and 4 oz. of carabao liver, when available, were added to the diet. The latter items seemed to have the most effect in arresting the development of corneal ulcers and in healing the manifestations of ariboflavinosis. By this time, also, a visual-test chart was made and batteries for an ophthalmoscope were obtained. Examination revealed pallor of the disc in the region of the papillo-macular bundle. Vision was reduced to 10/200 on the average, by December, 1942, and usually remained stationary thereafter, although in some cases, a slow decline continued. Central vision was most affected. Fields showed central and cecocentral scotomas, with moderate constriction of the peripheral fields.

At this point, one of us (S. M. B.) was transferred to Santo Tomás, a camp for Allied civilian internees. Here an opportunity arose to observe the effect of early treatment in conditions similar to those afore described. These people had fared better up to that time by being allowed to receive or purchase food from the neutrals and Filipinos outside. They were not dependent on the Japanese ration, which was just as inadequate as at Cabanatuan. However, the Japanese closed all traffic with outside sources on February 1, 1944, and by May, patients were complaining of photophobia, retrobulbar pain, and diminution of vision, particularly in bright light. Small supplies of thiamin chloride were available from the American Red Cross shipment of August, 1943 (delivered to the internees January, 1944), so that we were able to give 25 mg. daily for two to three weeks to affected individuals. This dosage served to check

the progress of the disease. Multiple vitamins were given along with injections of the thiamin. A patient who had lost 80 pounds in 12 months at Fort Santiago (Political Military Prison) and who had developed beriberi as well as a diminution of vision to 10/200 with central scotomas, made a fair recovery over a period of eight months during which he was treated as has been outlined. By November, 1944, he was able to read large print and his own handwriting. His vision returned to 20/70. In December, 1944, be-

Hospital with complaints of: (1) decreased vision in both eyes, (2) inability to see an object when using central vision, (3) burning and pain in the extremities.

On admission to this Hospital, his appearance was that of a well-developed and well-nourished man. (His history has been related.) The physical examination performed by the Medical Service showed no abnormalities or variation from normal. Neurologic examination was entirely negative except for: (1) peripheral neuritis and (2) optic atrophy, bi-

cause of the marked starvation (the diet was down to 200 gm. of polished rice daily), his vision began to deteriorate again.

In Santo Tomás, colored visual fields were charted. Patients showed earliest changes in the blue field; then changes in the red and green fields, enlargement of the blind spot, constriction of peripheral fields; later, central or cecocentral scotomas became evident.

OBSERVATION OF LIBERATED PRISONERS IN THE EYE CENTER

To give a detailed report on each case studied at this Eye Center would be unnecessary repetition, for all the cases fall into a uniform pattern in their essential findings. These data will be presented in the chart, showing the minor variations in each case.

Typical case. The patient entered the

lateral. Laboratory work consisted of: (1) basal-metabolism rate, (2) electrocardiogram, (3) blood chemistry, (4) electro-encephalogram, (5) cephalin flocculation, (6) X ray of lungs and heart, (7) routine urinalysis, (8) blood count, (9) serum reactions. All of these tests were normal. Stool examination revealed intestinal parasites.

The eye examination was as follows: The external examination revealed normal lids, conjunctiva, sclera, and cornea. The lacrimal apparatus was patent, and tactile tension normal. External ocular movements were full, and the pupils reacted to light and accommodation. No lacrimation or photophobia was present. On slitlamp examination, the cornea appeared normal, with no increase in limbal vascularization, no degeneration, no thinning, and no xerosis. The iris stroma, lens, and anterior vitreous were normal

throughout. The anterior chamber was of normal depth; the aqueous ray was absent. No cells were seen. With well-dilated pupils, the ophthalmoscopic examination showed clear media. No elevation nor abnormal excavation of the optic-nerve head was seen. The edges were clearly defined and distinct. The temporal portion of the disc showed a definite pallor, whereas the nasal portion was relatively normal. The vascular tree was normal, and the periphery of the fundus revealed no pathologic lesions. The macular area appeared normal in approximately 60 percent of the cases and mottled in 40 percent. Vision in each eye was 20/200, not correctable. The peripheral fields showed mild, generalized constriction, but were not remarkable. The central fields showed a central scotoma of 5 to 8 degrees, with a 1-degree target under good illumination, and a centrocecal scotoma, either absolute or relative, with a 0.5-degree target. The scotomas were larger for colors than for white.

A diagnosis was made of optic atrophy secondary to nutritional deficiency.

Treatment consisted of a high-vitamin, high-caloric diet, supplemented by daily administration of six multivitamin capsules, thiamin (50 mg., intramuscularly), and riboflavin (10 mg.). This treatment was instituted for a 60-day period. After this course of treatment, a reexamination showed no change in any case.

COMMENT

The description given is that of a typical case, and the following discussion will deal with the variations.

Cornea. Five patients showed small corneal scars resulting from ulcers that occurred in 1942, and one showed a complete leucoma following a perforating ulcer suffered at that time. All other corneas were clear.

Discs. The color of the discs varied from a minimal temporal, to almost complete pallor, but the vast majority showed only mild temporal pallor. The most striking feature was the lack of correlation between the visual acuity and the extent of the optic atrophy.

Maculas. The maculas, as has been stated, were normal in 60 percent of the cases, while 40 percent showed macular mottling and loss of foveal reflex.

Central fields. The central fields (figs. 1, 2) varied only in size and in the density of the scotomas, the latter depending on the severity of the condition.

Vision. The vision varied from 20/40 to 2/200 and varied directly with the density of the scotoma.

Extrinsic factors. As seen in the chart, there were many factors which had a definite influence on the final vision retained. These factors were as follows: (a) Patients having the most severe cases of malnutrition died; at this Center we dealt with the less severe cases. (b) Of this group, the men from Bataan seemed to have suffered more than the men captured on Corregidor because of the lack of supplies to the Bataan force prior to capture. They showed definite signs of malnutrition and early beriberi before surrendering, but had no eye complaints that we know of. (c) The diets of the various prison camps played a paramount role in determining the end result. At Bilibid and Cabanatuan, the diets were most deficient, consisting mostly of rice and soup from cancong weed. Here the inmates showed the most marked pathologic changes. At the other extreme, prisoners at some camps in the southern portion of Japan proper showed much less change because their rice diet was supplemented with fish, fresh fruit, and occasional meat. It is interesting to note that three patients with no pathologic eye findings (not included

in this report), were imprisoned in camps where the diet approached normal. In most camps, the rice served was polished. However, in at least one instance, the rice polisher broke and unpolished rice was served for two months. A definite improvement in the condition of the men resulted during this time. On returning to the diet of polished rice, they suffered a recurrence of former symptoms. The men state that the prisoners who refused to eat the cancong soup, and those bartering their food for cigarettes, suffered more severely than others.

Another important factor was the presence of severe malaria, dengue fever, and dysentery (bacillary and amebic). These diseases caused marked debility and anorexia which prevented the ingestion of what little food was allowed them.

From time to time, the men were able to supplement their diets with vitamins obtained in various manners, and a temporary improvement in their condition was noted at such times. The most striking example of this was seen when a marked improvement in symptoms among all prisoners followed the administration of a small amount of Red Cross supplies in December, 1943.

DISCUSSION

A group of patients is presented that has had an extremely unusual and unfortunate experience. These men have been under conditions of malnutrition and avitaminosis for a long period of time and give accurate histories of severe loss of weight, extreme weakness, and symptoms of diseases due to lack of food and vitamins. Since liberation, they have all been on diets high in calories and rich in vitamins, with recovery from all symptoms except those referable to nerves and eyes.

During the onset and development of amblyopia (from May, 1942, to November, 1942), their diet consisted of from 200 to 400 gms. of polished rice a day and watery soup made from cancong weed. Later, small amounts of other vegetables, fruit, fish, and meat were added, but the diet was always far from adequate. Polished rice is very low in thiamin (trace to 0.5 μ mg. per gm.), and the cancong soup contained a negligible amount. Two hundred to 400 gm. of rice furnish approximately 700 to 1,400 calories, so that the total caloric intake per day was probably 900 to 1,600 calories. Not only was the caloric intake low, but the ratio between thiamin ingested and total amount of calories consumed was also abnormally low. Cowgill,¹ in 1934, showed that a definite relationship should exist between total caloric intake and thiamin ingested, and that when this is not normal, symptoms of deficiency developed. Besides this abnormal relationship there was another. In "Vitamin therapy" by Gordon and Severinghaus,² it is stated that the thiamin requirement of man is dependent on the proportion of fat to carbohydrate in the diet. Fat has a thiamin-sparing action, whereas carbohydrate increases the need for thiamin. On looking at the diet described, we find rice to have 79.3-percent carbohydrate, 0.26-percent fat, 7.1-percent protein; therefore, the need for thiamin is very apparent. In 1942, at Mayo Clinic, Williams, Mason, Smith, and Wilder³ gave the requirements of thiamin for man. They stated that, on .07 mg. thiamin per 1,000 calories, patients had weight loss and noted increasing weakness. They also found that the minimal daily requirements of thiamin for man was between 0.22 and 0.50 mg./1,000 calories providing CHO/fat ratio was normal. The diet these men were on had insufficient thiamin requirements, had an

abnormal thiamin/caloric ratio, and an abnormal fat/CHO proportion which necessitated increased thiamin. This all shows that a definite thiamin deficiency was present.

Another observation to be made is the similarity of our findings to those of Carroll's^{4,5} and Johnson,⁶ who reported cases of tobacco-alcohol amblyopia which they believed due to thiamin deficiency. In both conditions, we see defective vision, central or cecocentral scotomas, normal peripheral fields, and temporal pallor of the optic-nerve head. In one paper,⁵ Carroll suggests that the amblyopia could be a "manifestation of a deficiency condition without toxic elements" or could be due to "toxic action of tobacco on malnourished cells." He further suggests that when B₁ is added, the nutrition of the damaged cells, or perhaps their axons, improves, and the injurious agent is no longer injurious. He also shows improvement in vision and fields on thiamin therapy. Our findings sustain the first premise, for no toxic element was apparently concerned. In another paper,⁴ Carroll shows a case in which the eye findings were almost identical to ours and which unquestionably improved on thiamin therapy.

Thiamin therapy was tried in all our cases but the results were poor. It is believed they were thiamin deficient so long that irreversible changes had taken place in the optic nerve. The peripheral neuritis in the extremities was not relieved, probably for the same reason. However, some of the patients not included in this report, because they were not blind, improved under parenterally administered thiamin therapy when given in early stages of the deficiency. Sufficient amounts were not available to treat all prisoners.

It is of interest to note that Moore⁷

describes a syndrome of misty vision, photophobia, and optic atrophy associated with glossitis, perleche, and itchy, scaly scrotum along with neuritic changes which closely resembled this disease in early stages. These patients were African sugar-plantation workers whose diet was very deficient. After the pellagra and ariboflavinosis cleared, vision, as well as symptoms of peripheral neuritis, remained unimproved. The symptoms and final end results closely resemble those experienced in the prison camps.

It is of possible importance that the men in our prisoner-of-war series claimed better vision in dim light, as in evenings, than in ordinary daylight. This is contrary to what one would expect in vitamin-A deficiency and, although adequate amounts of cod-liver oil were available and given, it failed to arrest the declining vision, which was evidence that some other factor was responsible. However, the vitamin A did result in healing of the corneal ulcers. The central scotomas, photophobia, and lacrimation were responsible for the poor vision in bright light. At night, the uninvolved retina would be expected to function more or less normally.

SUMMARY

The early eye findings in American soldiers while in Japanese prison camps and residual findings in some of these men after liberation have been presented. The following conclusions are drawn:

1. Malnutrition due to a deficient diet can cause an optic atrophy manifested by defective vision, central or centrocecal scotomas, and pallor of the nerve head.

2. The deficiency seems to be due to a lack of vitamin B₁, since the diet, in every case, was highly deficient in this vitamin; the symptoms occurred coincidentally with beriberi; and the symptoms were re-

lieved by thiamin when administered in the early stages of the deficiency.

3. If treatment is not instituted early enough, the condition becomes irreversible, as witnessed by the lack of improvement after administration of intensive vitamin therapy at this Center.

4. The loss of vision and the size of the central scotomas were not in direct proportion to the amount of optic atrophy seen.

5. The appearance of the disc varied from minimal to complete atrophy, with

the vast majority of eyes showing mild temporal pallor.

6. The maculas had a normal appearance in 60 percent of the cases and a mottled appearance with loss of the foveal reflex in the remainder.

7. The nerve involvements—peripheral neuritis and optic atrophy—were the only residual abnormal findings made at this Center on patients who had suffered severe malnutrition over a period of years.

CHANGES IN THE ANGIOSCOTOMAS ASSOCIATED WITH THE ORAL ADMINISTRATION OF EVIPAL*

AUSTIN I. FINK, M.D.[†]

Brooklyn, New York

INTRODUCTION

For some time ophthalmologists have been concerned with the question as to whether barbiturates are contraindicated in the treatment of patients with glaucoma. This concern has derived to a great extent from the fact that large doses of barbiturates have been known to produce a dilation and to increase the permeability of the cerebral blood vessels and capillary bed.^{1, 2}

With a suitable method, one could study the effect of an orally administered barbiturate upon the retinal vascular system. Angioscotometry was chosen as a suitable method for this experiment, since changes in the normal angioscotoma are assumed to represent alterations in the functions of the retinal perivascular space.

METHODS AND MATERIAL

The word "angioscotoma" signifies a "defect in the visual field related in form to the pattern of distribution of the retinal vessel tree."³ These shadows (after extensive research) have been interpreted as arising because of modifications of the retinal perivascular spaces and in the retinal synaptic junctions.⁴

Technique. The scotoma was mapped according to the method advocated by Evans.⁵ The defects in the visual fields

could thus be studied both qualitatively and quantitatively.

The Evans stereocampimeter and charts were used. Monocular fixation was employed throughout the experiment. The diameter of the spherical, white test object used was in all cases 0.4 mm. (illumination of the test chart was approximately 15 foot-candles). The blind spot of Mariotte was outlined. Then the two main superior angioscotomas were plotted by moving the object from seeing to blind, care being taken at all times to move the test object at right angles to the border of the defect.

Subjects. Ten studies were carried out on 10 different subjects, 9 female and 1 male. The ages of the subjects ranged from 21 to 26 years. All known causes for alteration of the angioscotoma were carefully eliminated. Each subject was found to be in good health.

Procedure. The subjects rested for approximately ten minutes before any mapping was begun. During this period the pulse and blood-pressure values were recorded. The subjects were familiarized with the apparatus and instructed to respond either by tapping with a pencil or by saying "gone" to indicate the disappearance of the test object. The first map or control was then plotted. The subject then took orally a tablet containing 4 gr. of evipal.[‡] This particular drug was employed because evipal is a rapidly acting barbiturate. Four grains is an average

adult hypnotic dose.¹ A second chart was plotted 30 minutes after ingestion of the tablet in order to allow time for beginning absorption. The pulse and blood-pressure values were again recorded. This same technique was employed at

demonstrable alteration of the scotoma. There was no change in the area of the blind spot. Pupillary changes were not detectable by available methods. The first effects of the drug were noted from 30 to 45 minutes after the barbiturate had been

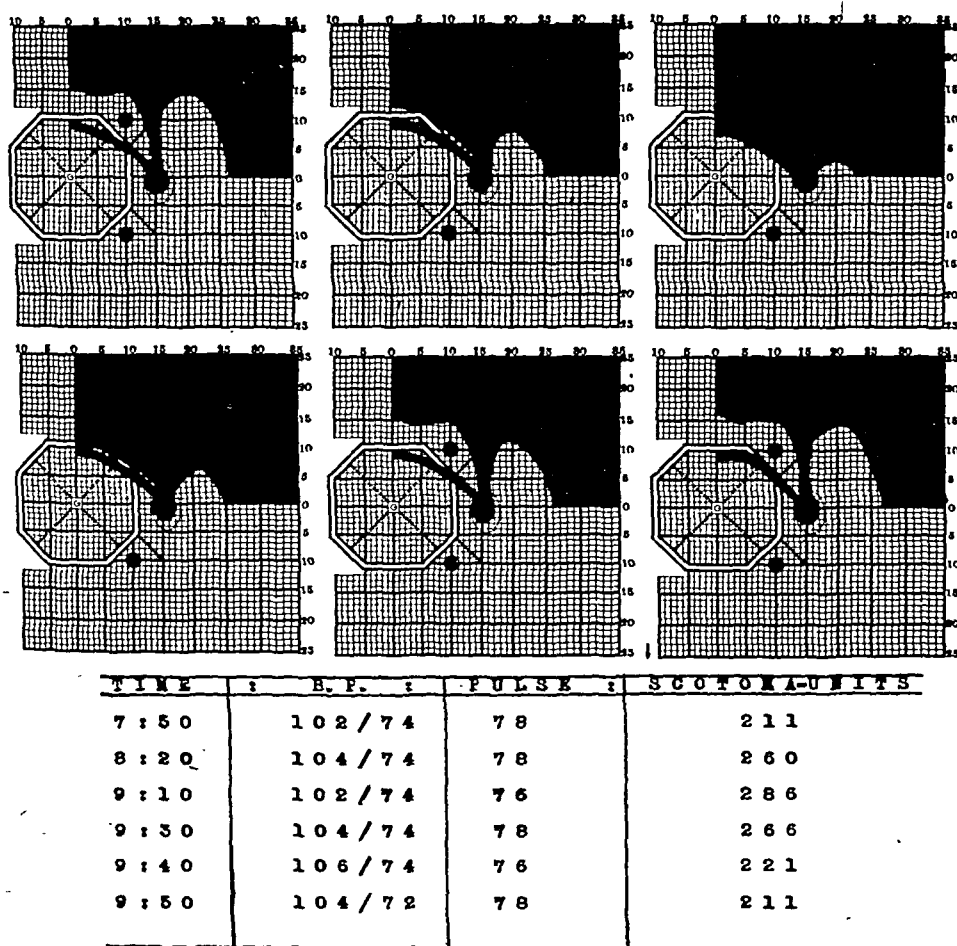

Fig. 1 (Fink). Angioscotomas plotted to show the effects on a subject (C. M.) after oral administration of evipal.

15- to 20-minute intervals until the control stage was once again reached.

OBSERVATIONS

The accompanying charts, table, and graph illustrate the observations made with the subjects. A widening of the angiogram was associated with the oral administration of evipal in 8 of the 10 subjects. The other two showed no

taken. The average time was 35 minutes. Maximum effects were obtained from 45 to 105 minutes following ingestion. The average time was 70 minutes. The effect was lost in 90 to 205 minutes after oral administration, the average time being 149 minutes.

No subjective sequelae, such as psychic depression, were noted in any of the subjects. The effect on the blood-pressure

and pulse rate did not vary significantly so far as could be observed.

COMMENT

In attempting to evaluate what was observed in this experiment, it will be necessary to state what is thought to be the

a fuse to protect the rod-and-cone layer (neurogenic or nerve-fiber-bundle hypothesis).⁵

2. The disturbance of the normal physiology of the retinal perivascular system (angiogenetic or perivascular-space hypothesis).⁵

TIME	B. P.	PULSE	SCOTOMA UNITS
8 : 00	140 / 90	72	200
8 : 50	140 / 88	70	242
9 : 45	140 / 84	66	292
10 : 25	136 / 86	68	250

origin of the alteration of any angioscotoma.

The influencing factors are thought to be:

1. Anything that would interfere with the conductivity at the synaptic junctions, because in the presence of deleterious agents the synaptic junctions may act as

3. The autonomic nervous system which relates the first hypothesis to the second.⁵ (Basic studies have been duplicated over the world by many workers and have been found in agreement.)

Evidence has been found in the literature to suggest that possibly each of the foregoing factors, in itself, may be con-

sidered as a partial explanation as to why the alterations of the angioscotomas took place in this experiment:

1. Microscopic sections of the brain from fatal cases of barbiturate poisoning have shown "a swelling or tumefaction of the ganglion cells."⁶ This observation

would lend support to that part of the neurogenic hypothesis.

2. In the introduction of this paper, it was stated that large doses of barbiturates have been known to produce a dilation and increase the permeability of the cerebral blood vessels and capillary bed.^{1, 2} It would not be unreasonable to assume that this dilation and increased permeability would alter the physiology of the perivascular space. This observation would then add support to the angiogenetic or perivascular-space hypothesis.

3. In studying the effects of evipal on the parasympathetic nervous system, Emelin has noted that "the effects are very similar to those caused by atropine. Evipal diminishes the responses obtained through a stimulation of the cholinergic nerves. It also counteracts the muscarine-like effects of acetyl-choline."^{7, 8} The parasympathetic nervous system, it seems,

Fig. 3 (Fink). Graph illustrating the effect of evipal administration, expressed in scotoma units.

also exerts its influence to bring about the changes of the angioscotoma.

In summarizing, one might say that any one, or a combination of, the three pieces of evidence just presented might account for the alterations of the angioscotoma found in this experiment. Doubtless there are other mechanisms.

It will be remembered that 2 of the 10 subjects did not exhibit any change in the angioscotoma following the ingestion of evipal, whereas others showed a marked alteration of the central visual field. This seems in accordance with variations found in different patients when barbiturates are employed clinically. Some show no response; others are markedly depressed or even exhibit excitation.

On a controlled series of five of the subjects, an experiment was carried out, in which capsules containing 4 gr. of lactose (milk sugar) were administered orally. The subjects did not know that the capsules merely contained a placebo. The purpose of the control was to ascertain whether a psychologic factor was present and helped to cause the alterations in the angioscotomas occurring after the subjects ingested evipal. The method,

technique, and procedure employed were identical with those used for the evipal studies. The results demonstrated that, in the series of five subjects, no alteration of the angioscotoma was recognized.

CONCLUSIONS

Under the conditions of these experiments and in the subjects tested the following conclusions were drawn:

1. The oral administration of 4 gr. of evipal was associated with a widening of the angioscotoma in 8 of 10 subjects. The other two showed no recognizable change.

2. Administration of a placebo containing 4 gr. of lactose to five of the subjects of the evipal series produced no alteration of the angioscotoma.

3. One might ascribe the associated effect of evipal on the normal angioscotoma as related to changes in: (a) the perivascular space functions; (b) conductivity of the retinal neurons and synaptic junctions; and (c) the parasympathetic nervous system.

The author wishes to express his sincere appreciation to Dr. John N. Evans for his guidance and encouragement during the preparation of this paper.

DISCUSSION

DR. FINK (closing): One thing that was revealed to me was the fact that evipal had any connection with the autonomic nervous system. At present, angioscoto-

metric studies are being carried out in our department on homatropine and atropine which should lend support to this observation.

THE ROLE OF LENS SUBSTANCE IN EXPERIMENTAL GONORRHEAL IRITIS*

MAURICE J. DRELL, M.D.

Seattle, Washington

MARJORIE BOHNHOFF, S.B., AND C. PHILLIP MILLER, M.D.

Chicago

INTRODUCTION

In the course of studies^{1, 2, 3} on experimental gonorrheal iritis in rabbits, it was noted that the infection was more severe and more likely to become chronic in eyes in which the lenses had been traumatized at the time of inoculation. The present study was undertaken in an effort to explain this observation and to evaluate the role played by lens substance in the experimental infection.

Ophthalmologists have long known that in human eyes the degree of inflammatory reaction and the incidence of suppurative complications are greater after extracapsular extraction than after the intracapsular operation or any other "clean" intraocular procedure. However, there has not been general agreement as to the factors responsible for this. Discussion of the pertinent literature might be considered under three categories: (1) immunologic reactions with lens; (2) the toxic effects of lens substance; (3) the lens with relation to infection.

The study of immunologic reactions dates from Uhlenhuth's paper⁴ showing, by means of precipitin tests, that lens protein was organ specific. This has, in the main, been confirmed by others (Hektoen,⁵ Bellows⁶) and has also been demonstrated by anaphylactic reactions (Kodama,⁷ Markin and Kyes⁸). The classic

paper of Verhoeff and Lemoine⁹ on phacoanaphylactic endophthalmitis and the findings of the Johns Hopkins investigators have established it as an entity explaining some of the cases of postoperative inflammation.

The toxic effects of lens substance. Straub¹⁰ developed the concept of phacogenetic endophthalmia, that is, inflammation caused by the presence of lens substance in the ocular fluids. Gifford¹¹ and de Roeth^{12, 13} demonstrated that normal lens substance in the anterior chamber was irritative, that cataractous lens substance was even more toxic, and that nucleus was more toxic than cortex. Injection into the anterior chamber of some of the amino acids present in the lens gave rise to varying degrees of inflammatory reaction. Lens substance was digested by trypsin for a day and the resulting material injected into the anterior chamber. These one-day digests caused no inflammation; two-day digests caused mild iritis; four-day digests, severe iritis.

Braun^{14, 15} found that lens substance could bring about contraction of the isolated smooth muscle of the guinea-pig uterus and had a vasodepressor effect not attributed to histamine or acetylcholine. Orlov,¹⁶ by the injection of portions of cataractous lens into the anterior chamber of rabbits, confirmed the greater toxicity of nuclear as compared with cortical material.

The lens as a factor in facilitating infection. This was our major concern in the present investigation. Many of the

* From the Department of Surgery (Division of Ophthalmology), the Department of Medicine, and the A. B. Kuppenheimer Foundation, The University of Chicago. Presented at the 15th scientific meeting of the Association for Research in Ophthalmology, Inc., at San Francisco, July 2, 1946.

standard treatises (Spaeth,¹⁷ Wiener and Alvis,¹⁸ von Blaskovics and Kreiker,¹⁹ de Schweinitz,²⁰ Meller,²¹ Norris and Oliver,²² Collins and Mayou,²³ and Clapp²⁴) make no mention of the relation between lens substance and infection. Czermak and Elschmig,²⁵ in discussing cataract surgery, advised the removal of the lens remnants and blood clots which form so suitable a medium for the multiplication of introduced bacteria.

De Wecker,²⁶ in 1883, commented on the greater likelihood of suppuration in operations where the lens capsule was incised than in noncapsulotomizing operations. He did not know why this was so, although he did not think that operative trauma played any important role.

Bacteria, in their effects on the intra-ocular tissues, were divided by Perles²⁷ into three large groups: (1) those that multiplied within the eye and caused inflammatory destruction of the organ—that is, panophthalmia; (2) those that did not persist within the eye but before their death caused noticeable inflammation; (3) those that caused no noticeable reaction. Bacteria of the second group, in larger numbers or with increased virulence, could cause panophthalmia; with a decrease in virulence, bacteria of the first group could cause self-limiting changes.

Chibret,²⁸ in 1888, found that *Staphylococcus aureus* was not able to survive *in vitro* either in water or in sugar solution, but did grow when lens substance was added. Leber²⁹ noted perforation of the lens capsule in experimental infection; he attributed this to the action of leucocytes rather than to bacteria or their products.

Andogsky,³⁰ in 1896, confirmed Chibret's findings and also inoculated the anterior chambers of rabbits with *Staphylococcus aureus* under various conditions. He found that anterior-chamber inocula-

tion of normal or of iridectomized eyes with small or moderate numbers of organisms resulted in a mild iridocyclitis; inoculation with large numbers of organisms resulted in perforation of the lens capsule and panophthalmia. However, inoculation of capsulotomized eyes with small numbers of organisms caused panophthalmia.

Hancock,³¹ in discussing the histopathology of postoperative infection, noted that the process was confined to the anterior segment and that considerable lens matter remained after extraction in the three enucleated bulbs he studied. He was of the opinion that a mild infection was present in most of the cases of severe reaction after extraction.

Treacher Collins³² demonstrated that lens capsule could heal in the lips of a corneal incision without causing inflammation. He also stated that aqueous humor containing lens substance was a good medium for bacterial growth. In the discussion, Elliot brought up the question of obstruction of the excretory channels by the viscid lens masses as an additional factor.

Lindner³³ called attention to the similarity of lens, skin, and mucous membrane as *epithelia*. He attributed to this the ease with which the pathogenic agents of epithelial tissue caused suppurative inflammation of the eye in the presence of free lens substance. Miklos³⁴ demonstrated that lens substance was, in general, a better medium for bacterial growth than was aqueous humor, meat extract, or blood serum.

In Velhagen's³⁵ case of purulent iridocyclitis, in which organisms considered to be gonococci were found in the eye, the lens capsule had ruptured and the organisms were particularly numerous in close proximity to the lens.

In the Lubarsch and Henke handbook, von Szily,³⁶ under the heading of septic

and experimental traumatic cataract, described in detail the histopathology of septic and aseptic wounds of the lens. Duke-Elder,³⁷ discussing purulent intraocular inflammations, called attention to the lens because of "the excellent culture medium which its substance provides for the growth of any type of organism."

To summarize the literature: In the first place, the lens has certain special immunologic properties; phacoanaphylactic endophthalmitis is a well-defined clinical and pathologic entity based on these properties. Secondly, the lens has some toxic effects; among its component parts, nucleus is more toxic than cortex, and cataractous nucleus is more toxic than non-cataractous. In the third place, there is abundant evidence that lens substance facilitates the multiplication of bacteria. It was toward a clarification of this latter problem with the gonococcus that our work was directed.

EXPERIMENTAL STUDIES

A. IN VIVO INOCULATIONS

Knowing that the lens was in itself toxic to some extent and also that it constituted a favorable medium for bacterial growth in general, we sought to determine what role these factors played in the development of experimental gonorrheal iritis. Several groups of experiments were performed. In one group, a suspension of gonococcus was inoculated into the anterior chamber of the rabbit. In a second group, sterile lens was injected; in a third, a mixture of gonococcus and lens. In a fourth group, gonococcus was inoculated, and the lens simultaneously injured with the hypodermic needle. As a control, in a fifth group, saline solution was injected and the lens injured.

The strain of gonococcus used was one isolated from a sulfathiazole-resistant

case of urethritis.* After three passages through the anterior chambers of rabbits' eyes, it was considered suitable for our purposes. Colonies were removed with a loop from the surface of the culture slant and were suspended in physiologic saline solution in a concentration of approximately 100 million organisms per c.c.

Lens substance was prepared in the following manner: The eye of a healthy young adult rabbit was enucleated, and the whole lens removed and placed in a test tube containing 5.0 c.c. of physiologic saline solution. The lens was broken up with a pipette, and the test tube shaken by hand for a few minutes. The resulting suspension had a turbid, opalescent appearance. It was bacteriologically sterile on culture and contained approximately 8 percent of lens substance as calculated from nitrogen determinations by the Kjeldahl method.

Gonococcus-lens mixture was prepared by breaking up a lens in a tube containing 5.0 c.c. of gonococcus suspension.

The volume of injected material was 0.2 c.c. The eyes were observed periodically, and careful descriptions were recorded. These were subsequently reduced, for purposes of tabulation, to symbols indicating the comparative severity of the intraocular reaction. After 8 to 14 days, the rabbits were killed, and cultures were made of the iris and lens.

Tables 1 to 5 summarize the appearance of the eyes and the results of autopsy cultures of the lens and iris. Zero (0) represents a normal eye. Plus-minus \pm signifies minimal exudation in the anterior chamber without grossly visible iridic hyperemia. One-plus (+) signifies

* The culture medium used throughout these studies was a casein-digest cystine agar.¹ For the recovery of gonococci from infected eyes, 10-percent fresh defibrinated rabbit blood was added.

a moderate amount of exudate in the anterior chamber and slight iridic hyperemia. Two-plus (++) signifies the presence of a small hypopyon, some corneal clouding, and moderate iridic hyperemia. Three-plus (+++) signifies a higher degree of corneal abnormality, a larger hypopyon, and intense iritic changes. Four-plus (++++) eyes generally show an almost opaque and greatly vascularized cornea, through whose more transparent central portions can be seen a hypopyon filling one third to one half of the anterior chamber.

Series 1. Gonococcus suspension was inoculated into eight eyes without injuring their lenses. Five of the eyes became normal in three to eight days; the other three showed one-plus reaction on the eighth day. The average reaction was a little less than one-plus. All post-mortem cultures were negative.

Series 2. Lens substance was injected into eight eyes without injuring their lenses. A maximal reaction of one-plus developed in one eye; the others showed zero to plus-minus reaction. By the fifth day all the eyes were normal. The first four eyes of this group were then used for Series 5.

Series 3. The gonococcus-lens mixture was inoculated into 24 eyes without injuring their lenses. Of the 20 eyes in which the ensuing process developed without complication, 16 had recovered clinically by the day the animals were killed, most of them by the seventh day; of the four eyes which did not, the reaction was one-plus in two, and two-plus and three-plus in one each on the day the animals were killed. The average reaction in these 20 uncomplicated eyes was closer to plus-minus than to one-plus. Of the four eyes in which complications devel-

oped, three became glaucomatous, with deep anterior chambers; in two of these, the glaucoma lasted long enough to cause enlargement of the bulbs; in the third, gross enlargement of the bulb did not develop. In the fourth eye of the group with complications, a rupture of the sclera occurred while it was being examined on the day after inoculation. Severe inflammatory reaction developed, and post-mortem culture revealed a gram-negative bacillus. Post-mortem cultures of the other 23 eyes were negative.

Series 4. Gonococcus suspension was inoculated into eight eyes with lens injury at the time of inoculation. These eyes showed, on the whole, a greater inflammatory reaction than those of any other series. When the animals were killed 11 days after inoculation, the reaction ranged from one- to four-plus in five of the eyes. The average reaction during the whole period was between two- and three-plus. The capsular rent in a sixth eye seemed to be healed on the third day, and the reaction had disappeared by the fifth day. The two remaining eyes became glaucomatous, the bulbs enlarging. One of these had an iris bombé; the other a deep anterior chamber. Of the eight eyes, two yielded a heavily positive culture of gonococcus from both the iris and lens.

Series 5. After they had recovered from the previous manipulation, physiologic saline solution was injected, with lens injury, into four eyes from Series 2. Three of the eyes became normal after four days, showing only one-plus reaction. The fourth eye showed persisting one- to two-plus reaction, and post-mortem culture revealed *Staphylococcus albus*. The other three eyes were sterile on culture.

The *in vivo* studies indicated that inoculation of gonococcus together with lens injury was necessary in order to effect a moderately severe inflammatory response. Inoculation, without lens injury, of gonococcus-lens mixture or of gonococcus

alone produced only a mild inflammation. Injection of lens substance or aseptic injury to the lens caused a minimal reaction.

B. IN VITRO STUDIES

In the preceding experiments, about four hours had been required to complete the inoculations. The substances used for inoculation were then cultured to rule out the possibility of bacterial contamination. The cultures indicated that more gonococci had remained viable in the suspension which contained lens than in the one which did not (fig. 1). Studies were accordingly undertaken to determine whether lens substance was able to prolong the life of gonococci in suspension.

Gonococci which had been grown over-

Ringer's solution for 48 hours at 4°C. The number of living gonococci was estimated by culturing serial 10-fold dilutions of each of the tubes. The suspensions were kept at 37°C. and cultures were repeated after 4 hours and 24 hours, and daily thereafter for 9 days.

The results are summarized in table 6. In the control tube, containing no lens, fewer gonococci were viable at four hours and none at one day. In the second tube, containing gonococci and fresh lens, no

A similar experiment was performed in which a fresh human lens was used. This was a simple senile cataract that had been extracted intracapsularly. The results are summarized in table 7. They were similar to those obtained with fresh rabbit lens. The control tube yielded negative cultures at one day, whereas the tube containing gonococci and lens showed a slight decrease at 24 hours, fewer organisms at two and three days, and none at four days.

Using a variety of solid and liquid media to which both fresh and autolyzed lenses had been added, attempts were made to obtain evidence of *in vitro* multiplication of the gonococcus in the presence of lens, as had been done by Miklos⁵⁴ with other microorganisms. These studies yielded negative results.

COMMENT

The gonococcus was recovered on culture only from that group of eyes (Series 4) in which the lenses had been injured

coccus aureus caused panophthalmia. We found that similar inoculation with gonococcus caused only a moderately severe anterior uveitis. The difference is probably due to the less potent pyogenic properties and the more selective cultural requirements of the latter organism.

As a pyogenic agent, the gonococcus occupies a position between groups 1 and 2 of Perles's classification of bacteria in relation to the eye. Ordinarily, a short-term infection results, the microorganism dies, and recovery occurs. Occasionally,

Technique and symbols as in table 6.

at the time of inoculation. Two of the eight eyes in this group yielded positive cultures. In a comparable group of eyes previously studied with the same strain,² the presence of gonococcus was demonstrated in 10 of 12 eyes either on culture or histologic examination. The organism used in the earlier studies had been passed through more than 40 rabbit eyes; it then seemed to be more virulent for the rabbit eye than in the initial stages of animal passage. It should also be pointed out that, in the meantime, the organism had been maintained on artificial media for over a year before the present study was initiated. Since these experiments were designed to compare the effects of gonococci injected under various conditions, three animal passages before use were sufficient.

Andogsky found that injury to the lens at the time of inoculation with *Staphylo-*

however, the gonococcus may be present in great numbers; or it may be so virulent as to cause disruption of the lens capsule (as in Velhagen's case); or post-operatively, sufficient lens substance may be present in the aqueous. Conditions then become favorable, and a severe infection results.

The rapid death of the gonococcus in the eye under ordinary circumstances, with the liberation of its irritative endotoxin, explains the self-limiting and acute nature of ordinary gonorrheal iritis. No allergy nor general toxemia need be postulated. The endotoxin is a poor stimulant of antibody production; this is probably why immunity is so slight and recurrences are so common.

In contrast with most other bacteria, the gonococcus is a fastidious microorganism, requiring certain specific conditions for its survival and multiplication.

Our *in vitro* studies indicated that lens, particularly after autolysis, greatly prolonged the organism's survival time. It has been demonstrated by Morax³⁸ that the survival of the gonococcus without multiplication varies with the individual strain and is in the order of three to nine days. We were unable to demonstrate any multiplication in our *in vitro* studies. McLeod, Wheatley, and Phelon³⁹ have demonstrated with some of the amino acids a favoring or inhibiting action on growth of the gonococcus. Further studies along this line would be of interest.

SUMMARY

The inoculation of gonococcus into the anterior chamber of the rabbit with lens

injury resulted in a moderately severe and chronic inflammation.

The inoculation of gonococcus without lens injury caused a mild inflammatory reaction. Inoculation of gonococcus-lens mixture without lens injury usually caused a similar reaction.

The injection of lens substance without lens injury or the injection of physiologic saline solution with lens injury caused only an insignificant inflammatory response.

Lens substance *in vitro*, particularly after autolysis, prolonged the survival time of gonococci. No clear evidence of multiplication was obtained under these conditions.

DISCUSSION

DR. S. JUDD BEACH (Portland, Maine): Dr. James H. Allen asks: "What was the time interval between injection of lens substance in Series 5 and the second inoculation of some of those eyes with injury of the lens in Series 5?"

DR. M. J. DRELL (Seattle, Washington): Five days, by which time the reaction from the injection of lens substance

had cleared completely.

DR. BEACH: Dr. M. J. Hogan asks: "Do you think lens substance exerts merely a protective effect on the organisms rather than acting as a culture medium?"

DR. DRELL: That question bothered us for a long time. Dr. Miller has been working with the gonococcus for many years, and the project originally was commenced

at the request of the O. S. R. D., in an effort to produce an experimental infection against which the sulfonamides and other therapeutic agents could be assayed. The gonococcus theoretically ought to grow in the presence of lens. We tried to make it grow but were unable to obtain any clear-cut evidence of its growth. We do know that lens substance is an excellent buffer; the suspension in which lens was present varied only slightly from pH 7.4 to pH 7.2 over a period of five days, whereas the pH of gonococcus suspension alone, in saline or in Ringer's, became acid, dropping from 7.4 to 6.8. This is probably one of the necessary factors. However, the lens also contains a great many of the nutritive agents on which the gonococcus should be able to live and multiply, and we were unable to demonstrate any multiplication.

The survival time of the individual gonococcus has been estimated by Morax to be between three and nine days, varying with the strain. The survival time of gonococcus in our study was eight days. Whether there was any multiplication of any sort during this period we are unable to say positively.

DR. TAUB: Dr. Kinsey wishes to know: "Were culture media tried containing glutathione or other sulfahydrides?"

DR. DRELL: The culture medium used was casein-digest cystine agar prepared in

the laboratory. It contained 0.065 percent of cystine, which I do believe is a sulfahydride.

DR. V. EVERETT KINSEY (Boston): Cystine or Cystein?

DR. DRELL: Cystine. This medium was used for the recovery of the organisms from infected eyes. Lens itself contains cystine, which is one of the reasons we thought that the gonococcus would be able to grow upon it.

DR. WALTER B. LANCASTER, chairman, (Boston): Will the essayist tell us whether injury to the lens or other optical injury occurs if the gonococci are introduced intravenously or somewhere outside the eye?

DR. DRELL: I presume the question refers to work similar to that reported by Dr. Rosenau with streptococci. I cannot recall any such investigations with gonococci with any positive results.

Perhaps another word should be added here. The attempt to produce the gonorrheal iritis is nothing new. It has been tried almost since the time that the organism was first described. The organism apparently needs to have its virulence enhanced in some way. The strain used by us was initially enhanced by something like 134 passages through the mouse peritoneum before it was sufficiently virulent for the purposes of producing this iritis.

SPONTANEOUS RUPTURE OF THE LENS CAPSULE IN ANTERIOR LENTICONUS*

LEON H. EHRLICH, M.D.

New York

Spontaneous rupture of the lenticular capsule has been reported as occurring in eight patients to date, in seven instances in association with senile cataracts, some of which had advanced to a morgagnian stage.

Apparently the first mention of this condition was by von Szily,¹ who, in 1884, reported a case of spontaneous rupture of the capsule and, at the same time, mentioned two similar cases by von Ulrich and von Arlt. Some 30 years later, in 1913, Rollet and Genet² published a case that occurred in a man, aged 67 years, whose left eye had undergone a successful cataract extraction approximately 12 years previously. The right eye, in which there was a milky (*laiteuse*) cataract, suddenly developed severe pain. Examination revealed a white fluid in the anterior chamber and increased ocular tension. The authors assumed that there had been a rupture of the capsule of the lens.

Gonzales,³ in 1919, described a woman, aged 75 years, in whose left eye he had noticed a mature cataract 14 years earlier. This eye became painful and, at examination, the anterior chamber was seen to be completely filled with a milky-white liquid. The pressure was much higher than normal.

Kaufman,⁴ in 1933, described the case of a man, 58 years old, who had been told 12 years before that he had a cataractous lens in his left eye. When seen, there was a three-day history of pain and redness of that eye. The upper eyelid was swollen. The anterior chamber was filled with a milky-white fluid which hid the details of the iris. Under slitlamp magnifica-

tion, cholesterol crystals could be seen in this fluid. The intraocular pressure measured 62 mm. Hg (Gradle-Schiøtz).

In 1937, Knapp⁵ reported the case of a woman, aged 67 years, with a blind eye, the condition of which had, at one time, been diagnosed as inactive choroiditis. Later, but 23 years prior to the rupture, a mature cataract was noted. Three months before Knapp's examination, one of the patient's relatives noticed an increase in the size of the white spot in the pupil. When seen, there was a mild pericorneal injection and a regularly dilated pupil which was filled with a white mass extending into the anterior chamber. The tension was recorded as 42 mm. Hg (Schiøtz).

The most recent case was reported by Box⁶ in 1941. His patient was the youngest to be reported with this condition. Since the age of 18 years, he was known to have opacities of both lenses which were thought to be congenital; their extent was not described. At the age of 34 years, an immature cataract reduced the vision of the left eye to perception of hand movements, with good light projection. About two years later, the patient returned with a history of improved vision in the left eye and deterioration of vision in the right. An iridocyclitis which the author regarded as of tuberculous origin was found in the right eye. The left eye appeared aphakic despite the absence of a history of trauma or surgery. X-ray examination showed no evidence of a foreign body. No corneal scar could be seen. Examination under the slitlamp revealed a temporal gap in the anterior lens capsule and some soft lens matter still present. After a needling op-

* From the ophthalmological service of Beth Israel Hospital.

eration was performed for the latter condition, corrected vision ultimately was 6/6 partly.

For completeness, another case may be added to this list. However, the element of trauma makes its inclusion in this series controversial. Beisbarth⁷ performed an iridectomy for secondary glaucoma on the eye of a woman, aged 65 years. Tension fluctuated between 25 and 37 mm. Hg (Schiotz), and there was an increased cloudiness of the lens. The eye seemed to tolerate the operation but five weeks later it became painful and, during the night, the patient experienced excruciating pain. In the morning, she said something had come out of the eye and brought to the ophthalmologist, as proof, a lens nucleus on a piece of gauze. Examination showed a small round hole at the limbus through which a tag of capsule appeared.

ANTERIOR LENTICONUS

Cases of anterior lenticonus are more frequent than rupture of the lens capsule. Only the literature on this subject that has appeared since the publication in 1934 of the paper by Rones⁸ will be mentioned here. He listed 10 recorded cases in which the diagnosis of anterior lenticonus appeared justified. In addition, he mentioned several other cases which he considered incorrectly diagnosed as lenticonus. Since then, a search has revealed 10 additional cases.

In 1936, Moulton⁹ described the case of a man, aged 33 years, who had bilateral lenticonus. Biomicroscopic examination showed that in each eye the anterior band of the lens and the anterior band of disjunction curved forward over the clear underlying contents of the conus. There was no alteration in their parallelism nor change in their thickness. The nucleus and posterior cortex of each lens were normal. A very few minute, delicate opacities were visible on the apex of the

cones and just beneath the intact anterior capsules.

Rauh,¹⁰ in 1936, reported the case of a man, aged 48 years, who had a lenticonus of each eye in which only the zone between the adult nucleus and the capsule bulged forward. The nucleus itself appeared normal in contour in each eye.

Knobloch¹¹ described, in 1937, anterior lenticonus developing in both eyes of a motion-picture operator, aged 20 years. According to an abstract, which was the only report available to the author, slit-lamp examination showed arching of the anterior capsule only, but not the limits of the surface between the detached zone and the cortical zone.

In 1939, Zavalia and Oliva¹² described the cases of two brothers, aged 23 and 15 years, in whom uncomplicated anterior lenticonus developed at puberty. The parents were cousins. This consanguinity and the presence of lenticonus in the siblings emphasized the role of heredity in this report, although apparently it played no obvious part in any of the cases described elsewhere. The older brother had lenticonus in both eyes. The condition was unilateral in the younger brother, but the fellow eye had an anterior-central capsular cataract. The illustration of the lenticonus in the younger patient showed an asymmetry in the protrusion of the anterior capsule and its underlying cortex which was not present in the regular curve of his brother's lenticonus. In this latter patient, there was seen a concavity in the usual convex surface of the anterior band of the adult nucleus corresponding to the lenticonus.

Ter-Artuniantz, Kotilianskaja, and Chutko¹³ reported, in 1939, two cases with all the symptoms of posterior lenticonus, but subsequently biomicroscopy demonstrated that one of these was a case of anterior lenticonus.

In 1940, Harris¹⁴ described the case of

a man who, for as long as he could recall, had had poor vision and was forced to leave school at the age of 16 because his sight suddenly and rapidly deteriorated. Slitlamp examination showed, in each eye, a globular protrusion of the anterior cortex and capsule through the pupil to within 0.5 mm. of the cornea. The anterior cortex and the capsule of each lens alone were implicated in the lenticonus. The nuclei were of normal configuration. However, just behind the center of the nucleus, were discoid punctate cataracts which were round and finely granular.

In 1942, Damel and Garbarino¹⁵ reported the case of a man, aged 24 years, whose vision had become poor when he was 15. He had bilateral lenticonus. The lens capsule and the anterior cortex presented the usual forward bulge, with a normal underlying nucleus.

Rocha and Coscarelli¹⁶ described, in 1943, a 30-year-old woman with bilateral lenticonus, the base of each cone being about 3 to 4 mm. in diameter. There were a few opacities of the coronary type, as well as some filaments of persistent pupillary membranes between the lens and the iris.

Marback¹⁷ published the most recent report in 1943. His case, occurring in a man aged 23 years, was one of microphakia with a lenticonus on the anterior face of each lens. The deformity involved the anterior capsule and the anterior half of the senile nucleus, the fetal nucleus appearing normal. The condition of the cortex was not described.

CASE REPORT

L. S., a boy, aged 12 years, was first seen on May 20, 1944, with a history of having worn spectacles for two years. He first realized that he had a defect of vision three years before, when his right eye became red after a mild blow received during a fist fight with another youngster. There was a history of nephri-

tis, hay fever, and asthma. Urinalysis showed the presence of albumin 2+, red blood cells, and casts. There was no edema. The blood pressure was 120/70.

Vision of the right eye was 4/200 and could not be improved. Retinoscopy revealed the characteristic appearance of a droplet of oil in the retinal reflex. The external and ophthalmoscopic examination presented no abnormalities. On examination with the slitlamp, there was seen a bulging forward of the anterior capsule in the axial region. The diameter of the bulge appeared to be 2.5 mm., and the elevation possibly one fourth the depth of the anterior chamber. This elevation seemed filled with a clear liquid which separated the anterior capsule from the lens substance. There was a very small amount of pigment on the capsule at the base of the elevated area (fig. 1).

The left eye appeared normal on external, ophthalmoscopic, and slitlamp examination. The reflex on retinoscopy was normal. There were 2.25 diopters of hypermetropia. Corrected vision was 20/20.

The patient was next seen a month later. At this time, the father said he had noticed, about a week and half previously, that there was a white substance in the pupillary region of the right eye. There had been no previous injury of any kind to either the eye or the head. Visual acuity was found to be reduced to the perception of hand movements. Soft lens material obviously protruded into the anterior chamber. Under the slitlamp, a tear could be discerned in the anterior lens capsule at the summit of the elevation. Swollen cortex presented through the tear into the anterior chamber (fig. 2). The intraocular pressure in each eye was 15 mm. Hg (Schiötz). Atropine was prescribed. It was decided to keep the eye under observation.

When seen three weeks later, the boy said that he had struck the right eye two days before. At this examination some of

the lens material was observed to have broken loose from the main mass, which was now larger than before, and was present in the lower part of the anterior chamber, descending almost to the angle. A few weeks later this separated lens substance had become absorbed. The area of opacification extended beyond the limits of the elevation of the capsule and spread about halfway to the equator of the lens. By November, the lens was almost entirely cataractous. An exotropia of about 20° was present. On January 26, 1945, a linear extraction of the cataract was performed, and the greater part of the lens washed out. Because of persistent pro-

trusion, could be made out under the slitlamp. After a year of progress, this gray area on the lens capsule showed con-

Fig. 3 (Ehrlich). External appearance a year later.

Figs. 1, 2 (Ehrlich). Slitlamp appearance of eye with anterior lenticonus. Fig. 1. Showing pigment at base of elevation. Fig. 2. Ruptured capsule.

trusion of the iris, a narrow iridectomy was made. A month later, vision of the right eye was 20/20 with a $+12D.$ sph. $\ominus +1D.$ cyl. ax. 180° .

While all this was taking place, changes began to be evident in the left eye. In September, 1944, a minute dot was seen in the anterior capsule. In the course of three months, two dots with a connecting line between, in a sort of dumbbell ar-

range enlargement and seemed to have the form of a horseshoe (fig. 3).

DISCUSSION

Spontaneous rupture of the lens capsule obviously will take place when the volume of the lens is greater than can be contained within the elastic capsule which, however, may stretch in compensation. Modifying factors will be: (1) Rapidity of the swelling; (2) variations of capsular tensile and elastic factors; (3) location of the swelling when not diffuse but confined to a portion of the lens.

That there is elasticity of the lens capsule to permit swelling was observed by Bowman¹⁸ who stated: "When removed from the eye and placed in water, the lens imbibes fluid through its capsule, which thereby becomes distended and separated from the contained lens, being raised in the form of a vesicle." Limitations naturally exist as to the amount of capsular stretching that can take place under such conditions, as has been shown by Bellows

and Chinn,¹⁹ who reported the spontaneous bursting of some lenses by swelling when subjected to various chemical solutions and altered physical conditions. One would assume that slow swelling, taking place over long intervals, would permit of greater volume without rupture of the lens capsule. This, however, can only be surmised. It is obvious that there is some limit to the extent of capsular enlargement.

The capsule increases in thickness with age. Whether this adds to or diminishes its tensile capacity cannot be stated. It is, perhaps, related to the diminution of its permeability with age as Friedenwald²⁰ has demonstrated.

Another theoretical consideration revolves about the possibility of the capsule sliding over the surface of the lens. If a small, localized elevation occurs anywhere on the lens surface, the overlying capsule will be subject to less strain if the entire capsule, or at least a large portion of it, shifts its position toward the region of the swelling. Otherwise, it is the portion of capsule immediately overlying the swelling that must bear the entire burden of adaptation to the new conditions, with a consequent increase in the possibility of rupture. When liquefaction of the lens substance occurs, increased pressure is distributed uniformly throughout the lens.

Alteration in the strength of the capsule undoubtedly occurs in the pathologic condition represented by morgagnian cataract. Duke-Elder²¹ apparently attributes to this factor the known cases of spontaneous rupture herein listed as well as the hypothecated ones wherein rupture is considered as being the possible explanation for some of the reported cases of spontaneous absorption of a morgagnian cataract, stating that they may be due to a rupture "in the thin capsular wall." Kaufman⁴ also has observed that the wall of the capsule is always thin in these cases. Under these conditions of

weakening of the capsule, a sudden increase in the intralenticular pressure or an alteration in relationship between the intralenticular and intraocular pressures could easily be the immediate and exciting factor in the rupture of the lens capsule. Ordinary daily activities and stresses or a sudden imbibition of fluid resulting from altered osmotic pressure relationships (possibly a result of disintegration of the lens protein) could increase or alter these pressures.

Senile and morgagnian cataract need not be the only varieties to provide the conditions for spontaneous rupture. Box's⁶ case occurred in the eye of a 36-year-old man, although it is possible that the morgagnian type of disintegration of the lens substance took place in the 27-month interval between the time when he was observed to have an immature cataract and when he returned manifesting a gap in the capsule of the partly absorbed lens.

Another case, more closely resembling the one here reported, is that of Feigenbaum.²² The patient was an Arabian youth with bilateral anterior lenticonus who, over a period of three years, had shown an increase in the lenticonus. When seen again, after another three-year interval, the right eye was essentially unchanged. Retinoscopy, however, revealed only a slight myopic astigmatism of the left eye in place of the 9 diopters of myopia previously present in the central portion of the lens. At this time, the patient said he had noticed a corresponding improvement in his vision. Biomicroscopy showed the protrusion to have been replaced by a somewhat dense subcapsular opacity at the same spot and of about the same size as the former lenticonus. Feigenbaum concluded that the increase in the convexity at the anterior pole "caused the capsule to burst in one place, resulting in a localized opacity, which means that a self-healing of the lenticonus

took place." Such a change from anterior lenticonus to anterior capsular cataract has also been described by Jaworski²³ and Tsukahara,²⁴ and both were attributed to a similar pathogenesis by Feigenbaum.

Jaworski's case was that of a 32-year-old man who had a bilateral lenticonus. When seen eight months later, there was present in the right lens a 2-mm. opacity in place of the lenticonus. In the left lens, there was a similar opacity, but a small amount of protrusion could still be made out. Unfortunately, this case was reported in the days before the slitlamp came into use, and so small capsular ruptures could easily be overlooked.

Rones⁸ believed that Tsukahara's second case does not properly belong with those called lenticonus, but it may well have been because the original article was published in Japanese, and the abstract in German does not give sufficient details to eliminate it definitively from this category. Tsukahara's first case obviously should not be included. His second case was of a 17-year-old boy with a unilateral lenticonus. Eight months later an anterior capsular cataract was added to this lenticonus. At this time the previously normal lens of the left eye also had an anterior capsular cataract. It is difficult to understand, on the basis of this meager information, how Feigenbaum can postulate a rupture in the lens capsule.

Review of the reported cases reveals two significant features: In every instance both eyes were sooner or later involved. This, in most instances, took the form of lenticonus in each eye. The exceptions are the younger of Zavalia and Oliva's two brothers, who had an anterior capsular cataract in one eye and lentiglobus in the other; the case of Tsukahara just described; and Feigenbaum's case after the disappearance of the lenticonus in the left eye.

The other feature is that the pathologic

process in almost every case involved the anterior capsule and cortex only. Of course, cases reported prior to biomicroscopy cannot be included. Exceptions to the localization of the pathologic process were: (1) the older of the two brothers described by Zavalia and Oliva who had a concavity in the normal uniform convex curve of the anterior band of the adult nucleus. (2) Harris's¹⁴ case presented, in addition to the lenticonus which involved only the anterior capsule and cortex, discoid punctate cataracts just behind the center of the nucleus. (3) Marback¹⁷ states that the deformity in his patient lay in the anterior capsule and the anterior half of the senile nucleus, the fetal nucleus being normal.

Ter-Artuniantz, Kotilianskaja, and Chutko's case¹³ is not included in the generalizations just made regarding bilaterality and the lack of nuclear involvement because the original article was not available and the abstract did not describe these features.

Any theory as to the origin of anterior lenticonus must account for the normal appearance of the nucleus. It is difficult to comprehend how a congenital disturbance would permit the nucleus to develop normally and make its effect felt only after puberty. The bilaterality of the lesion and the lack of a hereditary tendency (only Zavalia and Oliva's brothers present such a factor) would point to a metabolic disturbance. The nephritis of the patients of Kienecker²⁵ and Jaworski²³ and the two constitutional elements of allergy and nephritis in the case here reported give some support to such an element in the causation of anterior lenticonus. In their articles, Rones⁸ and Bellows²⁶ both discuss the various theories of the causation of anterior lenticonus, which need not be repeated in this report.

Although the accuracy of the diagnosis of anterior lenticonus in the case herein described may well be questioned, there

seems to be no other described condition that corresponds to it more closely. Vogt's atlas,²⁷ as well as the smaller one of Meesmann,²⁸ illustrates no similar case, nor is one included in Bellow's recent encyclopedic work on cataract and lenticular anomalies.²⁹ The process in the right eye seems similar to the one Feigenbaum²² described as occurring in the left eye of his patient except that the rupture in the latter case must have been much smaller. If the anterior capsular change of the lens of the left eye which developed during the period of observation had been present when the patient was first seen, it would have appeared essentially the same as that of the younger of Zavalía and Oliva's patients. In Tsukahara's case, the anterior capsular cataract also developed during observation. The spontaneous improvement in both eyes of Jaworski's patient, within an interval of only eight months, indicates the

rapidity with which such a change may occur. Our patient was seen only by chance in the interval between the breakdown and liquefaction of the lens substance in the lenticonus, when rupture of the extended and strained capsule was imminent and before the actual rupture of the membrane took place.

SUMMARY

A case of anterior lenticonus in a boy is described. It is unusual in that it was unilateral; that the cone contained liquefied lens material; and that it ruptured spontaneously. During the period of observation, the left eye developed central-anterior capsular changes.

The literature on spontaneous rupture of the lens capsule and on anterior lenticonus has been summarized and discussed in relation to the case here reported.

CONTUSION CATARACT OF THE ANTERIOR LENS CAPSULE*

HERBERT F. SUDRANSKI, M.D.

Indianapolis, Indiana

CASE REPORT

The traumatic cataract described by Vossius¹ is thought to originate from the deposit of uveal or blood^{2, 3} pigment upon the anterior lens capsule at the pupillary margin when the iris is forced against the lens by contusion of the globe. A recent case of perforating injury of the eye presented a cataract of similar etiology. This cataract involved the anterior lens capsule only. A perfect, although very faint, imprint of the circular sphincter pupillae muscle fibers and of the radial markings of the iris was stamped upon the anterior lens capsule. It contained no pigment, and was a much more complete reproduction of the iris anatomy than the pigmented ring or arc which marks the site of the pupillary margin upon the anterior lens capsule in cases of Vossius-ring cataract. This lenticular opacity appears to be a unique variety of traumatic cataract not yet reported in the ophthalmic literature.

History. D. M. D., an aviation machinist mate, aged 20 years, was examined on August 2, 1945, to determine his fitness for sea duty. His medical record confirmed a remarkable history of trauma to his right eye. On December 3, 1944, while he was engaged in cleaning a metal lathe with a medium-pressure air line (50 lb.), he was struck in his right eye by a blast of air when, for a moment, he lost control of the hose. Two days later he reported to his sick bay, complaining of pain and redness of his right eye. Corneal ulceration was noted at the 8-o'clock position, with cloudiness of the cornea below. Ophthalmoscopy revealed a triangular, metallic foreign body lying within the vitreous in the lower temporal aspect of the fundus. Roentgen examination showed two metallic foreign bodies, in the lateral view, in line with the orbits. These were not visualized in the posterior-anterior view.

* From United States Naval Hospital, Astoria, Oregon. The opinions or assertions contained herein are the private ones of the writer and are not to be construed as official or reflecting the views of the Navy Department or the Naval Service.

At the United States Naval Hospital, in Oakland, California, it was noted that the patient had a healed, perforating wound of the cornea at the 9-o'clock position. Beneath this wound, the iris was

punctured, and there was a visible track through the lens. Six disc diameters along the inferior temporal vessels, a shiny foreign body, measuring one disc diameter in length and one-fifth disc diameter in width, was visible upon ophthalmoscopy and appeared to be located 1 mm. from the retina. Roentgen studies failed to show any foreign body in or near the right eye. Conservative treatment, consisting of the instillation of atropine and application of heat locally, was followed. By January 2, 1945, the right eye was free of pain and all visible signs of inflammation. After 30 days, there having been no appreciable change in the condition of the right eye, the patient was returned to duty.

Examination. When this patient was examined in August, 1945, bilateral vision was 20/15. The left eye, upon external examination, palpation of the intraocular pressure, and ophthalmoscopy, was entirely normal. The right eye showed a penetrating scar of the cornea located at the 9-o'clock position, 2.0 mm. within the limbus. It was 0.5 mm. in width and 2.0 mm. in length, being directed obliquely upward toward the corneal vertex. Slightly above the corneal wound and just within the limbus, there was a faintly atrophic scar of the iris which measured 1.0 mm. in width and extended vertically 2.0 mm. No track could be located within the lens. The ocular tension to palpation was normal. By focal illumination and by biomicroscopic examination with diffuse direct illumination, a complete reproduction of the circular sphincter pupillae muscle fibers and of the radial pattern of the iris was observed to have been laid down upon the anterior lens capsule, in faint, grayish-white markings. These markings were confined to the lens capsule and contained no pigment. The biomicroscope showed no other lenticular pathologic

change, but revealed a finely granular disorganization of the vitreous in the zone immediately behind the lens. Ophthalmoscopy showed no pathologic lesion in the ocular media other than the corneal scar. The cataractous changes of the anterior lens capsule and the vitreous disorganization were invisible. The fundus was essentially normal, although its lower temporal region showed very slight disturbance of the retinal pigment. No trace could be found of the previously reported metallic foreign body.

Roentgen report. The Hospital roentgenologist made the following report: "There are two minute, opaque foreign bodies in the region of the right orbit. The first measures approximately $1.0 \times 1.0 \times 0.25$ mm. It is extraocular in location. The second measures approximately $1.0 \times 0.5 \times 0.25$ mm. It lies 11.5 mm. below the horizontal plane of the cornea, 4 mm. to the temporal side of the vertical plane of the cornea, and 13 mm. behind the center of the cornea; therefore, it lies in or close to the sclera."

DISCUSSION

This case has several features of unusual interest. It would appear that the retained metallic foreign body was either completely absorbed or that it was extruded from the eye by migration through the sclera. The absorption of foreign particles within the eye (for copper) was first reported by Leber⁴ in 1892. Fifty years earlier Castelnau⁵ had reported the migration of intraocular foreign bodies through the sclera. Extrusion of such a particle, according to Cordes and Harrington,⁶ is accompanied by ocular inflammation with softening of the sclera. Since, in this case, all inflammatory reaction had subsided within the 30th day after the accident, the foreign body remaining visible to ophthalmoscopic examination all the while, it would appear that transcleral migration

had not occurred. However, after the accident, two metallic foreign particles were visualized by X-ray examination. Again, when this patient presented himself for examination for fitness for sea duty, seven months later, two metallic foreign

gory of traumatic cataract not previously described. Impact of the iris against the lens, due to the application of tremendous force to the eyeball, has effected permanent alteration of the tissue of the anterior lens capsule. This alteration of
